PREFACE

The *Treatise on Geophysics* is a comprehensive and in-depth study of the physics of the Earth and of terrestrial-like planets residing both within and outside our solar system. Its breadth and detail of coverage are beyond what any single geophysics text can provide. The first edition of the *Treatise on Geophysics* was published in 2007, nearly a decade ago. Of course, there is much progress in science in that length of time and the field of geophysics has grown rapidly and developed new lines of inquiry. Accordingly, we have brought the *Treatise on Geophysics* up-to-date with this second edition. The new edition will continue to provide students and professionals with fundamental and state-of-the-art discussion of all aspects of geophysics. In this new edition, the reader will find updates to all the chapters contained in the first edition and new chapters that discuss topics missing from the first edition. In a few instances, chapters from the first edition have simply been reprinted in order to avoid gaps in coverage. Chapters that emphasized fundamental physics often required little updating.

A highlight of the second edition is a new volume on Resources in the Near-Surface Earth. The new volume discusses the role of geophysics in the exploitation and conservation of natural resources and the assessment of degradation of natural systems by pollution. The near surface is a zone where humans and natural systems interact. Understanding the effects of human impacts is a challenge particularly for the long term.

There are four new chapters in the volume on Deep Earth Seismology. One of them describes progress in seismic instrumentation in the last 30 years in the era of broadband digital sensor and recording systems. Another one addresses a new approach for the determination of crust and uppermost mantle structure, based on ambient noise cross-correlations. This has revolutionized the field, since it allows the study of regional structure at high resolution in areas where there are no earthquakes. The third new chapter is devoted to recent advances in characterizing the lithosphere–asthenosphere boundary under both oceans and continents. Finally, the last new chapter discusses the morphology of subducted slabs in the Earth's transition zone.

The Mineral Physics volume has new chapters on dynamic (shock-wave) compression methods, and on the mineralogy of the upper mantle and the D″ layer focusing on post-perovskite, and extrasolar super-Earths.

New material in the Geodesy volume expands the temporal resolution and latency of geodetic measurements to high-rate, real-time measurements and increases the spatial resolution to meter size pixels with optical and radar imaging systems. Application areas are extended with new material on the uses of Earth gravity measurements.

The Earthquake Seismology volume has a new chapter on rock mechanics that is a comprehensive account of modern rock mechanics with emphasis on the variation of frictional properties of rocks during an earthquake cycle. Many chapters have considerable updates reflecting the lessons from significant recent earthquakes (e.g., the 2011 Tohoku-Oki earthquake and the 2013 Okhotsk deep earthquake), new observations on slow slips and triggered earthquakes, and developments of new methods (e.g., back projection method). Some chapters are updated (e.g., paleoseismology and strong ground motion) with substantial new material.

Chapters in the Geomagnetism volume have been updated to include recent advances in the acquisition of larger data sets and higher quality data and in the construction of more reliable and sophisticated models. Improvements in data have occurred in areas such as magnetic anomalies, paleointensities, and planetary magnetism. Improvements in models of the present day field include so-called comprehensive models and models that incorporate data assimilation.

The Crustal and Lithosphere Dynamics volume has new contributions on mountain building and landscape evolution.

The Mantle Dynamics volume contains new chapters on the generation of plate tectonics from mantle convection and the core–mantle boundary region.

The Core Dynamics volume features a comprehensive update of this rapidly changing subject, including new chapters on turbulence and waves in the fluid outer core.

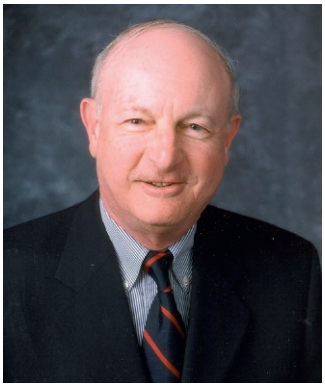
The volume on the Evolution of the Earth presents a new assessment on the role of volatiles in Earth evolution.

There are new chapters in the Physics of Terrestrial Planets and Moons volume on planetary atmospheres, planetary tectonics, extrasolar planets and asteroids and comets. The study of extrasolar planets has had explosive growth in the last decade and new spacecraft missions have significantly enhanced our knowledge of solar system planets and moons.

Finally, this is an opportunity for me to thank and acknowledge the editors of the individual volumes for their hard work, patience, dedication, and commitment in bringing this new edition of the Treatise to fruition. I am also indebted to Gemma Tomalin of Elsevier for her care and attention to the organization and production of the Treatise and to Deepa Arumugam for her careful coordination of the proofs from the copyeditor and typesetter. Of course, the authors of the individual chapters are the ones who are responsible for the excellence of the Treatise. We have all had some ups and downs in the process of producing the second edition of the Treatise but the final product is one that we can all view with pride.

Gerald Schubert
Editor-in-Chief

EDITOR-IN-CHIEF



Gerald Schubert is Distinguished Professor Emeritus in the Department of Earth, Planetary and Space Sciences at the University of California, Los Angeles. His research interests encompass the physics of the interiors and atmospheres of the Earth, the Moon, and the other moons and planets of the solar system. He is co-author with Donald Turcotte of *Geodynamics* (ed. 3, Cambridge University Press, 2014) and with Turcotte and Peter Olson of *Mantle Convection in the Earth and Planets* (Cambridge University Press, 2001). He is the author of over 540 research papers. He has participated in a number of NASA's planetary missions, including Apollo, Pioneer Venus, Magellan, and Galileo, and has been editor and editorial board member of many journals, including *Icarus*, *Journal of Geophysical Research*, *Geophysical Research Letters*, and *Annual Reviews of Earth and Planetary Sciences*. Professor Schubert is a Fellow of the American Geophysical Union and a recipient of the Union's James B. MacElwane medal and the Harry H. Hess medal. He is a member of the National Academy of Sciences and the American Academy of Arts and Sciences.

10.01.1 Introduction

Humanity has always been fascinated with the wandering stars in the sky, the planets. Ancient astrologists have observed and used the paths of the planets in the sky to time the seasons and to predict the future. Observations of the planets helped J. Kepler to formulate his laws of planetary motion and revolutionize the perception of the world. With the advent of the space age, the planets have been transferred from bright spots in the sky to worlds of their own right that can be explored, in part by using the in situ and remote sensing tools of the geosciences. The terrestrial planets are of particular interest to the geoscientists because comparison with our own planet allows a better understanding of our home, the Earth. Venus offers an example of a runaway greenhouse that has resulted in what we would call a hellish place. With temperatures of around 450 °C and a corrosive atmosphere that is also optically nontransparent, Venus poses enormous difficulties to spacecraft exploration. Mars is a much friendlier planet to explore but a planet where greenhouse effects and atmospheric loss processes have resulted in a cold and dusty desert. But aside from considerations of the usefulness of space exploration in terms of understanding the Earth, the interested mind can visit astounding and puzzling places. There is the dynamic atmosphere of Jupiter with a giant thunderstorm that has been raging for centuries. There is Saturn with its majestic rings, and there are Uranus and Neptune with complicated magnetic fields. These giant planets have moons that are astounding. There is the volcanic satellite of Jupiter, Io, that surpasses the Earth and any other terrestrial planet in volcanic activity. This activity is powered by tides that twist the planet such that its interior partially melts. A much smaller moon of Saturn, Enceladus, also has geysers that could be powered by tidal heating although the case is less clear. Its volcanic activity releases water vapor not lava, however. There is another moon of Saturn, Titan, that hides its surface underneath a layer of photochemical smog in a thick nitrogen atmosphere, and there are moons of similar sizes that lack any comparable atmosphere. Miranda, a satellite of Uranus, appears as if it has been ripped apart and reassembled. And Triton, the major satellite of Neptune, has geysers of nitrogen powered by solar irradiation. Magnetic field data suggest that icy moons orbiting the giant planets may have oceans underneath thick ice covers. These oceans can, at least in principle, harbor or have harbored life. Moreover, there are asteroids with moons and comets that may still harbor the clues to how the solar system and life on Earth formed.

This volume of the Treatise on Geophysics discusses fundamental aspects of the science of the planets. It is focused on geophysical properties of the Earth-like planets and moons, those bodies that consist largely of rock, iron, and water, and the processes occurring in their interiors and on their surfaces. But it goes further by discussing the giant planets and asteroids and comets as well and other extrasolar planetary systems. The better part of the volume is dedicated to the formation, interior structure, and evolution of the terrestrial planets and to their physical properties such as gravity and magnetic fields, rotation, the physics of the atmosphere, and surface–atmosphere interactions. What is the planetological context of life and are there feedbacks between life and planetary evolution? An attempt at answering these questions is the subject of a dedicated chapter. In the second part, we turn to the outer fringes of the solar system beyond the asteroid belt, to the giant planets and their satellites, to Pluto and the Kuiper Belt, and, finally, to extrasolar planets. Because exploration by spacecraft is so fundamental to the geophysics of the planets, the volume has two chapters that discuss the orbital dynamics – the routes to the planets – and the instruments typically flown on planetary missions. This edition of the volume has been widened in scope and coverage in comparison with the previous editions with dedicated chapters on asteroids and comets, on planetary tectonics and volcanism, on planetary atmospheres, and on extrasolar planetary systems.

10.01.2 Our Planetary System

The solar system contains a myriad of bodies ranging in size from the Sun to miniscule dust particles. The *Encyclopedia of Planetary Sciences* (Shirley and Fairbridge, 1997; on the web as part of the *Earth Sciences Series* at www.springerreference.com), *Encyclopedia*

of Astrobiology (Gargaud et al., 2011), and *Encyclopedia of the Solar System* (Spohn et al., 2014); Vol. VI-4-B of the Landolt–Börnstein Series (Trümper, 2009); the Planetary Scientist's Companion (Lodders and Fegley, 1998); and textbooks such as de Pater and Lissauer (2010) are useful sources of information about the solar system. Valuable collections of planetary data can be found on http://science.jpl.nasa.gov/PlanetaryScience, on http://ssd.jpl.nasa.gov, and on http://nssdc.gsfc.nasa.gov. A collection of images of planetary surfaces can be found in the NASA Photojournal (http://photojournal.jpl.nasa.gov).

The eight planets Mercury, Venus, Earth, Mars, Jupiter, Saturn, Uranus, and Neptune are shown in **Figure 1** together with Pluto, the most prominent member of a new class of objects, the dwarf planets. The International Astronomical Union (IAU) introduced the class of dwarf planets in 2006. These are intermediate in size between the terrestrial planets and the 'small solar system bodies' such as cometary nuclei and most asteroids. The IAU has so far identified the following five celestial bodies as dwarf planets – Pluto, the asteroid Ceres, and the trans-Neptunian objects (TNO) Eris, Haumea, and Makemake – but there should be many more still to be recognized dwarf planets in the solar system (e.g., http://en.wikipedia.org/wiki/List_of_possible_dwarf_planets). A planet of our solar system according to the IAU resolution 5 (http://www.iau.org/news/pressreleases/detail/iau0603/#1) is a celestial body that (a) is in orbit around the Sun, (b) has sufficient mass for its self-gravity to overcome rigid body forces so that it assumes a hydrostatic equilibrium (nearly round) shape, and (c) has cleared the neighborhood around its orbit. A dwarf planet according to the resolution satisfies (a) and (b) but has *not* cleared its neighborhood and (d) is not a satellite. All other objects, except satellites – so the resolution continues – shall be referred to collectively as 'small solar system bodies.' See also Basri and Brown (2006) for a discussion of the term 'planet.'

The Sun, a middle-aged main sequence star, contains 98.8% of the mass of the solar system but only 0.5% of its angular momentum. The next smaller body, Jupiter, still 300 times more massive than the Earth (see **Table 1**), contains more than 60% of the mass of the rest. Jupiter is the biggest of the *giant planets*, a group of gaseous planets that constitute a major subgroup of the solar system and other known planetary systems (see **Chapters 10.16** and **10.21**). Among the giant planets are, in addition to Jupiter, Saturn, Uranus, and Neptune. The latter two are sometimes called the subgiants or the ice giants because they are notably smaller than Saturn and Jupiter and because they mostly consist of water, methane, and ammonia, components often collectively called the planetary ices (see below). The Earth, the biggest member of the other major subgroup, the *terrestrial planets*, is the only planet on which we know to date that life has originated and evolved. Among the members of this group are Mercury, the innermost planet; Venus, the Earth's twin with respect to size and mass; and Mars. The latter planet has the best chance of having – or having once had – some primitive forms of life, which makes it a prime target of present-day space missions. The terrestrial planets together have about 0.005% of the mass of the solar system. **Table 1** collects some data of general interest on the planets, dwarf planets, and some major moons.

Comparative planetology is the science of studying the planets by comparing and finding general properties and common lines of evolution as well as features that are specific. It uses the methods of the natural sciences and is strongly interdisciplinary. Comparative planetology is not restricted to the planets *sensu stricto* but also considers the major moons of the planets such as the Earth's Moon, the major satellites of Jupiter (Io, Europa, Ganymede, and Callisto; **Figure 2**), the major Saturnian satellite Titan, and, finally, Triton, Neptune's major satellite. Other bodies of interest include the yet largely unexplored members of the asteroid belt, the asteroids, the comets, and the Kuiper Belt

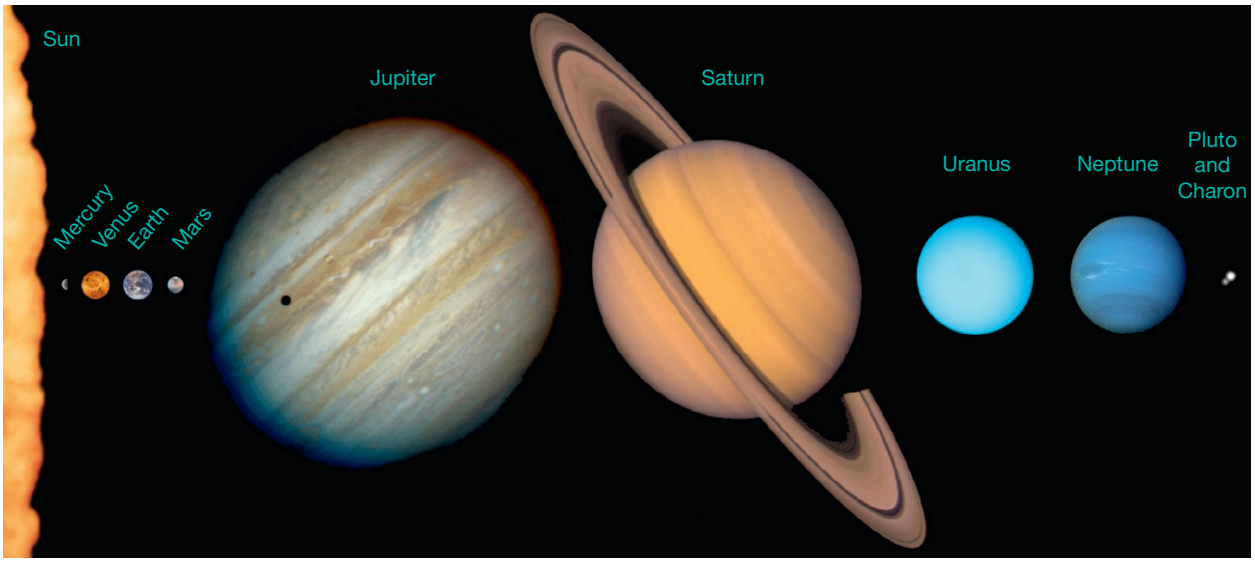

Figure 1 The eight planets Mercury, Venus, Earth, Mars, Jupiter, Saturn, Uranus, and Neptune and the dwarf planet Pluto are shown in this compilation of NASA images with their correct relative sizes and ordered according to their distance from the Sun. Mercury is barely visible at left close to the arc of the surface of the Sun, and Pluto is barely visible at the outer right. The dark spot on Jupiter is the shadow of Io, one of its major satellites. © C. J. Hamilton.

Table 1 Some data of general interest on the planets, dwarf planets, and some major moons

(a) Properties of the planets

	Terrestrial or Earth-like planets				*Giant planets*			
	Mercury	*Venus*	*Earth*	*Mars*	*Jupiter*	*Saturn*	*Uranus*	*Neptune*
Radius (km)	2438.0	6052.0	6371.0	3390.0	71492.0	60268.0	24973.0	24764.0

(c) Properties of major satellites

	Moon	*Io*	*Europa*	*Ganymede*	*Callisto*	*Titan*	*Triton*
Primary	Earth	Jupiter				Saturn	Neptune
Radius (km)	1737.4	1821.5	1562.1	2632.3	2409.3	2575.5	1352.6
Mass (10^{20} kg)	734.9	893.2	480.0	1481.9	1075.9	1346.0	214.0
Density (10^3 kg m^{-3})	3.344	3.53	3.02	1.94	1.85	1.881	2.061
Specific heat flow (pW kg^{-1})	8	890	150(?)	?	?	?	?
Orbital period (d)	27.32	1.769	3.551	7.155	16.69	15.95	5.877[b]

For the sake of space, we give four significant digits even for numbers that are more accurately known.
The uncompressed density is model dependent and cannot be given with more than 2–3 significant digits.
[a]A day (d) is equivalent to 24 h.
[b]The motion (rotation, revolution) is retrograde.
[c]AU is one astronomical unit or 149.6 million kilometers.
[d]A year (a) is equivalent to 365 days (d).
Source: The data have been taken from the compilation of Lodders and Fegley, The Planetary Companion, Oxford University Press, 1998, from Spohn, Planetologie, in Bergmann-Schäfer, Lehrbuch der Experimentalphysik, Vol. 7, (ed. W. Raith), W. De Gruyter, Berlin, p. 427–525 and from http://nssdc.gsfc.nasa.gov and http://ssd.nasa.gov.

objects. The asteroid belt is found between Mars and Jupiter, and its members are generally accepted to be the parent bodies of most meteorites (stones from space found on the Earth's surface; see Chapter 10.15). The Kuiper Belt stretches between 30 AU (roughly the orbit of Neptune) and at least 50 AU and contains the dwarf planets Pluto, Haumea, Makemake, and Eris (Chapters 10.19 and 10.20). The asteroids are believed to be the source of most meteorites and contain rich information about the formation of the solar system and its evolution and even the evolution of matter before the formation of the solar system. The Kuiper Belt objects are largely unexplored. Pluto, the most prominent member, and the Kuiper Belt are the target of the New Horizons mission launched in 2006 and scheduled to arrive at Pluto in 2015 (see Chapters 10.19 and 10.20). The emerging field

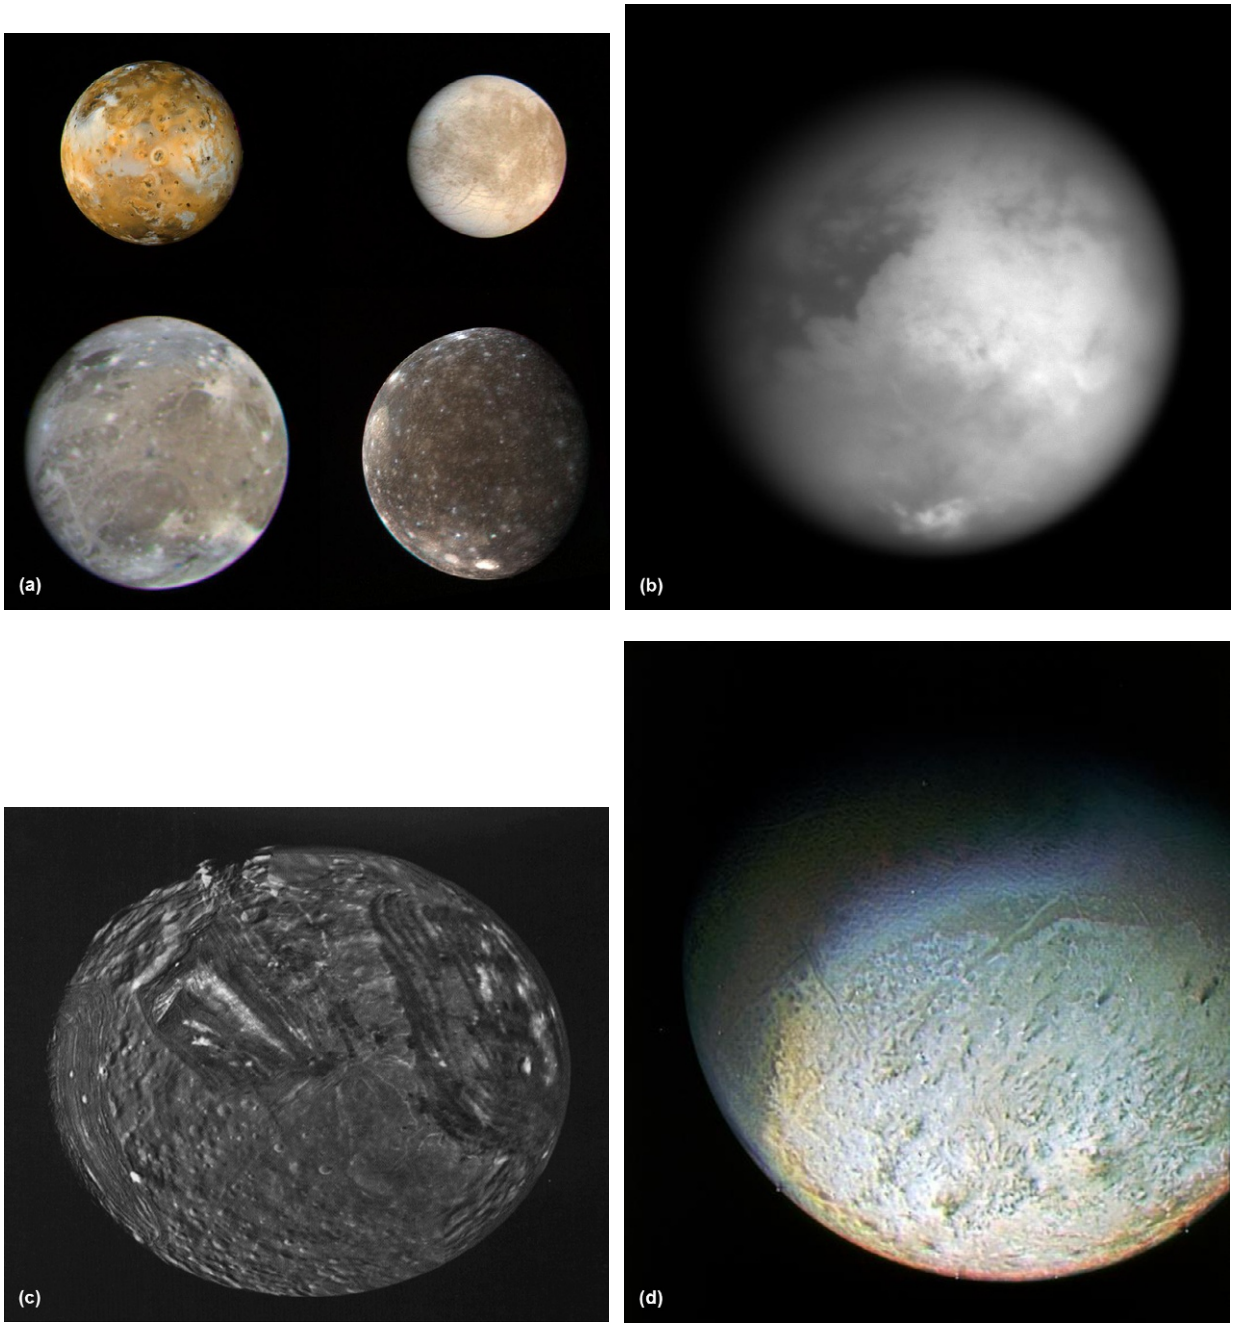

Figure 2 The four Galilean satellites of Jupiter Io, Europa, Ganymede, and Callisto (a), the Saturnian satellite Titan (b), the Uranian satellite Miranda (c), and the Neptunian satellite Triton (d) are shown in this compilation of spacecraft images from top left to bottom right. NASA/JPL.

of extrasolar planetology will further widen the scope of comparative planetology.

10.01.3 Planetary Missions

The results of planetary sciences have been made possible at their present levels only through the exploration of the solar system with space missions (see, e.g., Burke, 2014 and **Chapters 10.22** and **10.23**. See also a list of missions to the planets in Spohn et al. (2014)). All planets and major satellites of the solar system have been visited at least by a flyby of a robot spacecraft. This is not true of the dwarf planets, but missions are on their ways to Pluto (New Horizons) and Ceres (Dawn). Dawn has orbited Vesta between July 2011 and September 2012 (Russel and Raymond, 2011 and **Chapter 10.15**) and is planned to go into orbit around Ceres in February 2015. New Horizons is planned to flyby Pluto and its satellites with closest approach in June 2015 (**Chapters 10.19** and **10.20**). Some, such as Venus, the Moon, Mars, Jupiter, and Saturn, have been

explored by orbiters and by landers. The Moon has even been visited by astronauts. It can be said without any doubt that space exploration has turned dim disks in the sky observable with telescopes into worlds of their own rights waiting for further, perhaps eventually, human exploration.

Space exploration began with missions to the Moon in 1959, characterized by the race to the Moon between the United States and the then Soviet Union. This race culminated in the landing of men on the Moon. For planetary sciences, the significance of the Apollo program lies mainly with the first sample return, the first seismic exploration of a planetary interior other than the Earth's, the first heat flow measurement, and the first geologic field trip on another planet. Although Apollo has not finally solved the puzzle of the origin of the Moon – some may argue that it can never be solved once and for all – it has provided a wealth of data and has made the Moon one of the best-known planetary bodies. Scientists continue to successfully explore the Apollo data as the recent discovery of water in lunar rock (Saal et al., 2008) and the seismic detection of the core (Weber et al., 2011) have demonstrated. Missions to the Moon have been accomplished by Japan, China, India, and ESA (Kaguya, Chang'e, Chandrayaan, and Smart-1). A recent highlight of geophysical exploration of the Moon has been the GRAIL (Gravity Recovery and Interior Laboratory) mission of NASA with two spacecraft doing gravity gradiometry (**Chapter 10.05**).

Highlights of Mars exploration include the Viking missions, the first landings on Mars; the Pathfinder mission, the first vehicle introducing mobility; Mars Express, the first European planetary mission *sensu stricto*; the Mars Exploration Rovers, MER for short; and the Mars Science Laboratory on the Curiosity rover. From a geophysics point of view, Mars Global Surveyor, which returned highly accurate maps of topography and gravity (Smith et al., 1999) and detected the remnant magnetization of old crustal units (Acuña et al., 1999), has been a particularly remarkable mission. The MER (**Figure 3**) have been doing the first geologic field trips on Mars for the past 10 years and detected on their now tens of kilometers long journey minerals that formed under humid conditions (Squyres and Knoll, 2005 and papers therein). The Mars Express mission detected methane on Mars, numerous morphological units that required water to form (**Figure 4**, **Chapter 10.11**) and showed that volcanic activity continued albeit at a low rate until the recent past (Neukum et al., 2004). Mars Science Laboratory/Curiosity, more massive than any previous planetary exploration rover and equipped with a most sophisticated payload, is exploring the Gale crater and has found evidence for a past environment well suited to supporting microbial life. The first *in situ* geophysical observatory InSight equipped with a very broad band seismometer (compare **Chapter 10.03**), a heat flow probe, and a magnetometer is scheduled for launch in 2016. The lander will use its communication hardware for radio science tracking of, for example, the rotation axis of the planet. A sample return mission to Mars continues to be high on the agenda of the planetary science community.

An important driver for Mars research is its potential habitability and the possible detection of life, extinct or extant. The Viking landers in the 1970s already attempted to find signatures of bioactivity but for most failed to do so. Beagle 2 onboard the European Mars Express Mission was built to search for bioactivity and would have been the first European lander on another planet had it not failed. The next attempt to directly detect biosignatures on Mars will be the ESA ExoMars rover rescheduled for launch in 2018.

Venus has been the target of very successful Soviet missions that included eight Landers (Venera 7–14). These landers survived in the highly corrosive atmosphere of Venus only for a

few hours but transmitted color photos from the surface that shape our image of the Venusian surface. Further highlights of Venus exploration have been the Pioneer Venus, Magellan, and Venus Express missions, which provided extensive data on the atmosphere of Venus and the first systematic mapping of the surface with radar and in the infrared (Figure 5). Since the atmosphere of Venus is optically thick, cameras are of little use at this planet for surface exploration but are used to study atmosphere circulation patterns.

Mercury, the innermost planet, was visited by two flybys of the American Mariner 10 mission targeted for Mars in the 1970s. But since March 2011, the NASA MESSENGER mission has been orbiting the planet and has provided a wealth of data. The next mission to the planet will be the ambitious European BepiColombo mission scheduled for launch in 2016 with orbit insertion in 2024 and with a planetary remote sensing orbiter and a second orbiter – provided by the Japanese space agency JAXA – to explore the Hermean magnetosphere.

The outer solar system was first explored by the Pioneers that flew by Jupiter (Pioneers 10 and 11) and Saturn (Pioneer 11) and subsequently by the very successful Voyager I and II missions. The latter flew by all four major planets of the outer solar system. In addition to exploring the planets, these spacecraft discovered rings at Jupiter and Uranus and explored the satellite systems and found Io to be the most volcanically active body in the solar system. The Voyagers for the first time allowed a detailed view of the rich phenomenology of icy satellite surfaces. After the Pioneer and Voyager flybys, orbiters were the next logical step in outer solar system exploration. The first mission in this class was Galileo that orbited Jupiter and plunged into Jupiter's crushing atmosphere in September 2003. The spacecraft was deliberately destroyed to protect the Jovian system, in particular Europa, from being polluted. Galileo discovered the magnetic field of Ganymede and evidence for oceans underneath the ice crusts of the Galilean moons Europa, Ganymede, and Callisto. On its route to Jupiter, Galileo discovered for the first time a moon (Dactyl) that is orbiting an asteroid (Ida) and observed comet Shoemaker–Levy crashing into Jupiter. Galileo imaged the Jovian satellites at much improved resolution and discovered several new ones. Comparison with Voyager images of volcanic features on Io showed significant modifications that had occurred in the roughly 20 years between the two missions. An instrumented descent probe released from the Galileo orbiter entered the Jovian atmosphere in December 1995 and provided the first *in situ* measurements of the state and the chemistry of a giant planet atmosphere shroud. The results of the Galileo mission are discussed in Bagenal et al. (2004). The NASA Juno mission scheduled to go into a polar orbit in July 2016 to study the planet's gravity and magnetic fields, its atmosphere dynamics, and its composition will revisit Jupiter. The Jovian satellites will be the prime target of ESA's JUICE (JUpiter ICy moons Explorer) mission in the 2020s. Among the most spectacular planned missions to the Jovian system is a lander mission for Europa either as a Russian contribution to the JUICE mission or as a NASA mission. The mission plans are driven by the perception that an ocean on Europa may be covered by a thin ice shell that can be drilled and by the possibility that life developed in this ocean. It is possible that water from this ocean may have surfaced through cracks in the ice shell and may carry chemical signals of a biosphere.

At the time of this writing, Cassini has been orbiting Saturn for a decade. Cassini has even topped the success of Galileo as an outer solar system exploration mission through its more advanced payload capabilities and longer mission duration. The Huygens probe supplied by the European Space Agency (ESA) descended through the atmosphere of Saturn's biggest moon Titan and successfully landed on the surface on 14 January 2005 to transmit the first images (color) from Titan's surface (Figure 6). Titan's atmosphere is optically thick like that of Venus. Huygens landed on a solid surface strewn with ice boulders. On its descent, it imaged rivers in which

Figure 6 First color image from Titan's surface. This image was processed from images returned on 14 January 2005, by ESA's Huygens probe during its successful descent to land on Titan. The rocklike objects just below the middle of the image are about 10 cm across. The surface consists of a mixture of water and hydrocarbon ice. There is also evidence of erosion at the base of these objects, indicating possible fluvial activity. © ESA/NASA/JPL/ University of Arizona.

hydrocarbons are flowing or have flowed in the past and a possible shoreline (Lebreton et al., 2005). Near-infrared data from the Cassini mission have been interpreted as showing cryovolcanoes on Titan (e.g., Sotin et al., 2005). Another highlight of the mission is the detection of active geysers on the small satellite Enceladus (Porco et al., 2006, **Figure 7**), the diameter of which is only 500 km, and a rift structure circling Iapetus along its equator (Porco et al., 2005). Cassini also returned gravity data that allowed models of the interiors of some of the smaller satellites (see **Chapter 10.18**). Most recently, Cassini gravity data taken at Enceladus have been interpreted to support the existence of the long speculated (partial) ocean that could feed the geysers (Iess et al., 2014). This ocean would not be global but extend underneath most of the southerly hemisphere and has been speculated to be another potential habitat. Cassini will continue to explore the Saturn system through the Cassini Solstice Mission until September 2017 and then plunge into Saturn. Mission ideas to follow in the footsteps of Cassini include dedicated Titan and Enceladus Explorers. Just as for the Europa missions, these

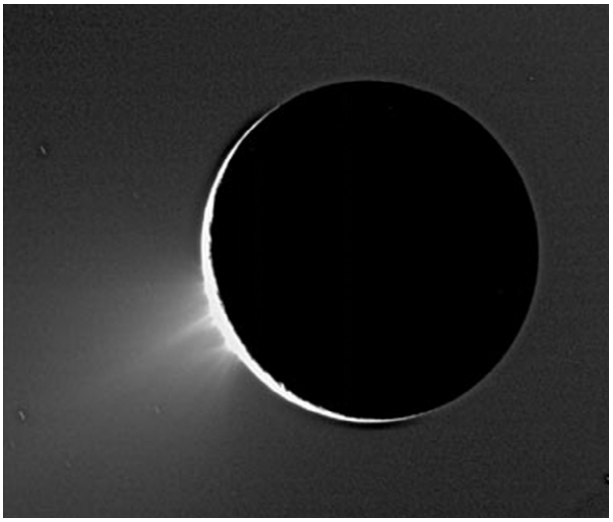

Figure 7 Geysers emanating from the southern hemisphere of Enceladus. NASA/JPL.

proposal are at least in part driven by the interest in possible extraterrestrial life.

Asteroids and comets are believed to be remnants of accretion and to consist of largely primitive matter (see **Chapter 10.15**). Although this perception is questionable to some extent – comet nuclei that have repeatedly flown by the Sun may have experienced thermal metamorphism; some asteroids show signs of endogenic activity and may be differentiated – asteroids and comets are minor solar system bodies of great interest. The Dawn mission has explored the second largest asteroid Vesta and is on its way to the dwarf planet Ceres. Vesta has been shown to be a differentiated body, while the latter could be undifferentiated and mostly primitive. Comet nucleus Churyumov–Gerasimenko is the target of the ESA Rosetta mission launched in 2004. After a 10-year cruise, the Rosetta orbiter and the lander Philae have ended hibernation and will begin to orbit the nucleus in late summer of 2014, while the lander Philae will dock onto the nucleus in the fall and explore it *in situ*. (We are speaking of docking rather than landing because of the small gravity of the nucleus.) Both the orbiter and Philae will take data as the comet approaches the Sun.

Planetary exploration has taken and is still following a stepped approach by which flybys are followed by orbiter missions. These are followed by lander missions including networks of landing stations and rovers. Sample return to the Earth is then foreseen, followed by human exploration. The latter step is often met with skepticism because of its prohibitive cost and is still facing huge problems of technical and medical nature and of safety for the astronauts.

The payloads of orbiters and flyby spacecraft are specifically designed for their science goals (see **Chapter 10.23**). It is still possible, however, to characterize generic payload elements that are typically found on these spacecraft. Almost every mission has at least one camera, often two for wide angle and for high resolution. Early missions had panchromatic cameras, but recent missions have color capabilities. Stereo is a useful feature that can increasingly be found on missions like Mars Express. Stereo allows 3-D imaging and enables the

development of digital terrain models. Digital terrain modeling is helped by laser altimetry as the successful Mars Observer Laser Altimeter (MOLA) on Mars Global Surveyor has so convincingly demonstrated. If the surface is hidden underneath an optically thick atmosphere, radar can be used to map the surface as has been successfully done at Venus by the Magellan mission. Radar is further used to map the surface roughness and to penetrate into the first centimeters of the near-surface layers, for instance, to look for ground ice. Other microwave sounders have been proposed that use different wavelengths and have differing depths of penetration.

While cameras, laser altimeters (**Figure 8**), and radio science instrumentation are indispensable instruments for planetary geology, geophysics, and geodesy, spectrometers are the tools of cosmochemistry and mineralogy. These instruments typically analyze particles (photons, neutrals, and ions) emitted from surfaces and atmospheres. Visible, near-infrared, and thermal infrared (0.5–15 μm) spectrometers are used to characterize the mineralogy of surface rock (silicates, carbonates, sulfates, etc.) and to search for water ice. Mapping infrared spectrometers such as Themis on Mars Odyssey and Omega on Mars Express allow a mapping of minerals on the surface. The Planetary Fourier Spectrometer on Mars Express works in a similar but broader spectral range (1.2–45 μm) but has a much higher spectral resolution at the expense of spatial resolution. Ultraviolet spectrometers measure neutral metals such as Al, Na, and S, ozone, and OH radicals. Gamma-ray spectrometers can measure radio nuclides (K, Th, and U), major rock-forming elements (O, Mg, Al, Si, Ca, Ti, and Fe), hydrogen (from water), and carbon, depending on the energy resolution and the elemental concentration in the surface. x-Ray spectrometers are suitable to detect the major elements Mg, Al, Si, Ca, and Fe.

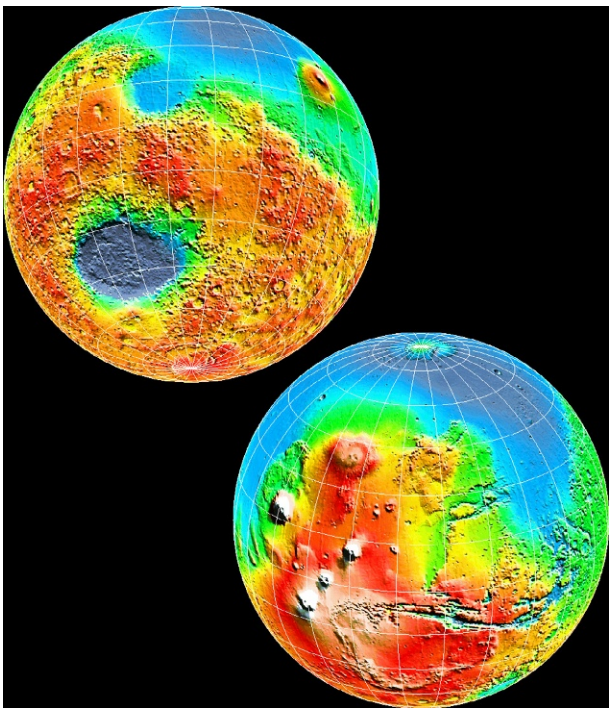

Figure 8 Global map of Mars taken by the Mars Observer Laser Altimeter (MOLA) onboard the Mars Global Surveyor mission. NASA/JPL.

The particles and electromagnetic fields surrounding planets and other solar system objects are measured with magnetometers and plasma detectors. Dust analyzers, finally, collect dust particles and analyze the direction and strength of dust flux in space.

Landing missions carry cameras and have been equipped with spectrometers and other sensors to measure composition and mineralogy. Mobility is an important issue since exploration of just one landing side may lead to biased results. Recent examples are the two MER rovers that carry a panoramic stereo camera, an alpha-particle x-ray spectrometer for elemental composition, a Mössbauer spectrometer for the identification of iron-bearing minerals, a miniaturized thermal infrared spectrometer for mineralogy, and a rock-abrasion tool to allow the measurement of 'fresh' rock (Squyres et al., 2003). Curiosity has a laser-induced breakdown spectrometer, an x-ray diffraction and fluorescence instrument, a neutron spectrometer, an environmental monitor package, a hand-lens imager, and a radiation assessment detector (Grotzinger et al., 2012). Network landers have not been flown yet but are generally agreed to be important (compare also **Chapter 10.03**). These landers will operate the same payload simultaneously at several locations. Applications are seismology to explore the interiors of planets, meteorology to explore planetary atmospheres, electromagnetic induction studies, and planetary geodesy. The NASA InSight mission will place a geophysical station on the surface of Mars in 2016. ESA is preparing for the ExoMars mission with the Pasteur rover to be launched in 2018 that will search for traces of extinct and extant life.

The search for extrasolar planets mostly uses two technologies, transit observations and radial velocity measurements through Doppler shift observations (see **Chapter 10.21**). While the former uses the slight dimming of the light of the central star as the planet passes between the star and the observer, the latter uses the Doppler shift of light from the star induced by the gravity pull of the planet on the star. Radial velocity measurements are done with ground-based telescopes or interferometers (such as the HARPS near Geneva, Switzerland, http://www.eso.org/sci/facilities/lasilla/instruments/harps.html) and constrain the mass of the planet. Transits are observed using ground-based and space telescopes such as COROT and Kepler and measure the radius of the planet. A planet observed with both methods can be characterized by an average density. Newly detected planets are candidates until they are confirmed by back-up observation. Several thousand candidates have been identified (most of them by Kepler), and roughly two thousand are confirmed. Future missions (such as PLATO (ESA) and TESS (NASA)) aim to detect planets of Earth size and smaller size orbiting bright stars and to do spectroscopy.

10.01.4 Planet and Satellite Orbits and Rotation States

There are some interesting commonalities between the orbits and rotation states of the planets and their major satellites. The rotation of the terrestrial planets is discussed in detail in

Chapter 10.04. The orbits lie mostly in a plane that is defined by the Earth's orbital plane, termed the ecliptic, and that is close to the equatorial plane of the Sun. The formal definition of the ecliptic plane adopted by the IAU calls for the ecliptic pole to be the mean orbital angular momentum vector of the Earth–Moon barycenter.

The normals to the actual orbital planes have inclinations relative to the ecliptic normal that are small, only a few degrees. The dwarf planets differ with orbital inclinations between 11° and 47° (Table 1). Small bodies (asteroids and comets) also tend to have larger orbital inclinations. The rotation axes of most planets and major satellites are within a few tens of degrees to the vertical to their orbital planes. Notable exceptions are Uranus, whose rotation axis lies almost in its orbital plane; Venus, whose retrograde rotation can be expressed as an inclination of almost 180°; and Pluto, whose inclination is between those of Uranus and Venus. The reasons for these anomalies are unknown but are sometimes speculated to be attributable to impacts of planet-size bodies on the young planets during the late stage of accretion.

The rotation and revolution of most planets and moons are prograde, that is, counterclockwise if viewed from above the celestial north pole. Exceptions are Venus, Uranus, and Pluto whose retrograde rotations can also be described as inclinations of more than 90° of their rotation axes to their orbital plane normals. Another exception is Triton, whose retrograde orbital motion about Neptune is unusual. Triton, like Pluto, is speculated to have originated in the Kuiper Belt. It was likely captured into its retrograde orbit by Neptune (see Chapter 10.17). There are many more satellites with retrograde orbits. However, these irregular satellites are typically much smaller than Triton, objects in a size range of only a few kilometers to a few tens of kilometers. The known rotation periods of the major satellites and of most satellites in general are equal to their orbital periods. This is termed a 1:1 spin–orbit coupling and is believed to be the result of tidal evolution (see Chapters 10.17 and 10.18). Tidal evolution occurs because planets raise tides on their satellites just as the Moon raises tides on the Earth. The gravitational force of the planet then pulls on the tidal bulge of the satellite. This torque will reduce the rotation rate of the satellite – should it be greater than its average orbital angular speed – and the interaction will end with the observed 1:1 coupling. As a result, the satellites present their primaries with mostly the same face at all times.

The planet Mercury is particularly interesting with respect to spin–orbit coupling since it is the only planet that is in such a resonance state with the Sun. However, its coupling is not 1:1, but 3:2 (see Table 1). The reason for this somewhat odd ratio is agreed to lie with the unusually large eccentricity of Mercury's orbit that has a value of 0.2 (Colombo, 1965; Chapter 10.04). Values of eccentricity <0.1 are more typical of planets and major satellites; the dwarf planets and small bodies have larger eccentricities. The large eccentricity of Mercury's orbit causes significant differences to arise between the constant rotational angular velocity and the orbital angular velocity that varies along the orbit. The two angular velocities could only be exactly equal at all times if the orbit were perfectly circular with zero eccentricity. The orbital velocity on an eccentric orbit increases towards the perihelion (the point of the orbit closest to the Sun) and decreases towards the aphelion (the point farthest from the Sun). Mercury's 3:2 resonance causes the orbital angular velocity to be equal to the rotational angular velocity at perihelion. This minimizes the tidal torque on Mercury and stabilizes the resonance.

The orbital distances of the planets from the Sun roughly follow a law with the distance of one planet to the Sun being roughly twice the distance to its inner neighbor. This rule is called the *Titius–Bode law* and works with Jupiter and Mars only if the asteroid belt is counted as a planet. The origin of the law is little understood. Regular relations between orbital distances or periods (the latter two are coupled through Kepler's third law of orbital motion) are not unusual in the solar system, however. The most prominent example is the Laplace resonance between the innermost three major satellites of Jupiter: Io, Europa, and Ganymede. A comparison of the orbital periods in Table 1 shows that these are in the ratio of 1:2:4. The origin of the Laplace resonance and its stability is attributed to tidal interactions between Jupiter and its three resonant moons. The orbits expand in the resonance as rotational energy is transferred through tidal interaction from Jupiter to Io and passed on in part to Europa and Ganymede (see Chapters 10.08, 10.17, and 10.18). The age of the resonance and how it formed are unknown. From the amplitude of libration, it has been concluded that the resonance is relatively young. Thermal-orbital modeling, however, suggests an age of at least 2 billion years (Fischer and Spohn, 1990). The tidal interaction and, in particular, the dissipation of tidal energy are believed to be the cause of volcanic activity on Io and of a subsurface ocean on Europa (Chapters 10.08 and 10.18). This ocean is completely covered by icebergs and ice shields that may slowly move relative to each other, and the ocean may even harbor, or may have harbored, primitive forms of life (see Chapter 10.14). The mathematical theory of tidal evolution is outlined in an appendix to Chapter 10.17.

10.01.5 Composition and Interior Structure of Planets

The chemical composition of the solar system is mainly dominated by the composition of the Sun, which has 98.9% of the mass of all bodies in the system. Although the compositions of the planets are different from that of the Sun, they are related to the Sun's composition and reflect varying degrees of depletion in volatile elements (see articles in Volume 1 of the Treatise on Geochemistry, Davis (2004)). The Sun is mainly composed of hydrogen and helium but contains all the other elements found in the solar system in abundances that are characteristic of the so-called solar composition.

Hydrogen and helium are dominant in Jupiter and Saturn, which are massive enough to keep these elements in molecular form against their tendency to escape to space. The potential of a planet to keep a specific element is measured by its escape velocity, which is proportional to the square root of the ratio between the planet's mass and its radius and must be compared with the thermal speed of an element, which is inversely proportional to its molecular weight (see Chapter 10.13). Still, Jupiter and Saturn are depleted in both H and He with respect to the composition of the Sun (Chapter 10.16). In addition to H and He, Jupiter and Saturn contain substantial amounts of water (H_2O), ammonia (NH_3), and methane (CH_4),

compounds collectively known as the planetary ices because of their occurrence on the surfaces of the major planets' icy satellites. In the deep interiors of the giant planets, these compounds are to be found in their supercritical forms for which there is no difference between the gaseous and liquid states. In addition to H, He, and planetary ices, Jupiter and Saturn likely have central cores of rock and iron. Models of the interior structure of planets can be constructed from a sufficiently detailed knowledge of their *figures* and their *gravity fields*. (The gravity fields of the terrestrial planets are discussed in Chapter 10.05; interior structure models of the terrestrial planets in Chapter 10.02. Chapter 10.04 discusses the rotation of these planets and how the rotation depends on interior structure. The giant planets are discussed in Chapter 10.16, while interior structures of giant planet satellites are discussed in Chapter 10.18) The construction of interior structure models is a primary task of planetary physics. Rotation deforms the planets from spheres into prolate spheroids. The flattening of both the figure and the gravity field is dependent upon the variation of density with depth. Unfortunately, these data do not allow unique models. The most accurate method of exploring interior structure is *seismology* (Chapter 10.03), the study of sound waves that travel through the interiors of planets and of global oscillations. This method is the prime method for exploring the Earth's interior to provide models of the variation of density with depth and also laterally by a technique that is known as seismic tomography (see Volume 1 of the Treatise on Geophysics). Seismometers, the instruments to record the waves, have been placed on the Moon during the Apollo program, and the interpretations of the results have provided important insights even up to the recent discovery of a solid inner core in the Moon (Weber et al., 2011). The InSight mission currently build by NASA in cooperation with CNES and DLR will place a state-of-the-art very broad band seismometer on the surface of Mars in 2016. The acoustic coupling between the surface and the atmosphere offers chances to do seismology from the orbit using cameras, infrared mappers, and ionospheric sounders. This method offers particularly good chances for Venus where environmental conditions on the surface are exceedingly demanding. The method can also be applied at the giant planets to study free oscillations and constrain interior models with these.

Models of the giant planets suggest that the outer layers of both Jupiter and Saturn are mostly H and He. H is molecular at moderate pressures but becomes metallic at pressures larger than 170 GPa (Figure 9). This pressure is equivalent to depths of about 14 000 km in Jupiter and 27 000 km in Saturn (Chapter 10.16). The phase transformation occurs at greater depth in Saturn because the pressure increases at a smaller rate in this planet due to its smaller mass. The deeper interiors of both contain the denser ices possibly in a shell above the densest iron/rock core. The cores plus the ice shells are believed to have masses that are quite uncertain, up to 45 Earth masses and radii of a few Earth radii.

Uranus and Neptune are further depleted in H and He and consist mainly of ice and the rock/iron component in addition to some H and He. Their structure, as the interpretations of the gravity field reviewed in Chapter 10.16 suggest, is not as clearly layered as those of Jupiter and Saturn. Rather, there appears to be a gradual increase of density with depth accompanied by a gradual increase of the abundance of ice at the expense of H and He followed by a gradual increase of the abundance of rock/iron at the expense of ice.

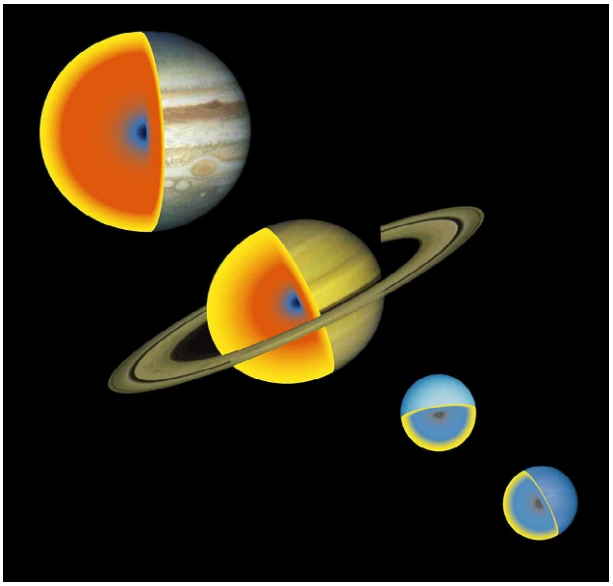

Figure 9 Interior structures of the giant planets. The yellow color indicates the molecular H and He shroud. Orange indicates the metallic H and He layers, blue is the range where the ice components are found, and the dark colors indicate the rock/iron cores. Courtesy of T. Guillot.

The major satellites of the outer solar system and Pluto also contain substantial amounts of ice, as their densities, around 2000 kg m^{-3}, suggest (see Table 1 and Chapters 10.18, 10.19, 10.20). Examples to the contrary, with substantially greater densities, are Io and Europa, the two innermost Galilean satellites of Jupiter. It is tempting to speculate that these two also started their evolution with a substantial abundance of ice. Io may have lost the ice completely and Europa to a large extent as a consequence of heating by impacts or as a consequence of tidal heating. Since Io and Europa are closer to Jupiter than Ganymede and Callisto, both the energy of impactors and the tidal dissipation rate will have been larger and may have caused the loss of water. But it is not clear that tidal heating could have provided the power needed to vaporize or partly vaporize ice layers on the two. However, it is also plausible that the temperature in the Jovian nebula from which the satellites formed was too hot at Io's and Europa's orbital distance to allow the accumulation of substantial ice shells. (The accretion of the satellites of Jupiter is discussed together with the formation of other satellites in Chapter 10.17) The Galileo mission has returned two-way Doppler ranging data that allow reasonable modeling of their interior structure (Figure 10). (See Chapter 10.18 for the icy satellites and Chapter 10.02 for Io. See also Chapter 10.23 for a brief discussion on the acquisition of radio science data.) Accordingly, Io has an iron-rich core of about half the satellite's radius and 20% of the satellite's mass with a rock shell above. Europa has a (water) ice shell about 150 km thick overlying a silicate rock shell and an iron-rich core. The nonuniqueness of interpretation of the data allows a wide range of sizes of these reservoirs, but the most likely radius values are 500–600 km for the core and 800–1000 km

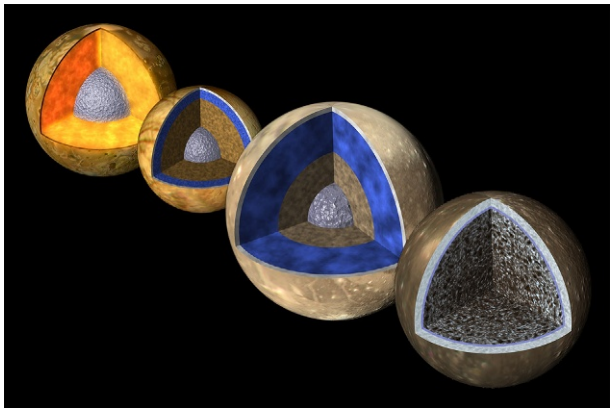

Figure 10 Interior structures of the Galilean satellites of Jupiter, Io, Europa, Ganymede, and Callisto (background to foreground).

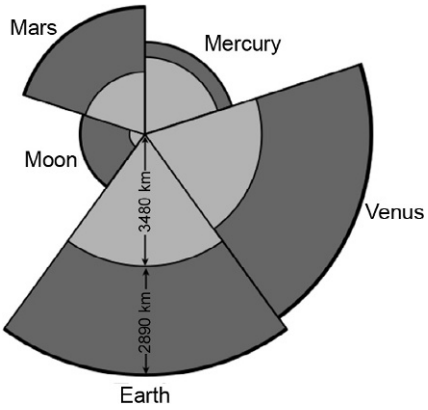

Figure 11 Basic interior structure of the terrestrial planets. To the first approximation, all terrestrial bodies possess a layered structure consisting of an innermost metallic core (light gray section), a silicate rocky mantle (dark gray layer), and a thin crust of volcanic origin, which is chemically distinct from the mantle (black layer not drawn to scale). While planetary radii are known precisely, core radii (light gray section) are not, apart from the case of the Earth's core, which consists of a liquid part surrounding a solid inner core (not drawn) with a radius of 1220 km. Reproduced from Tosi N, Breuer D, and Spohn T (2014) Evolution of planetary interiors. In: Spohn T, Breuer D, and Johnson TV (eds.) *Encyclopedia of the Solar System*. Amsterdam: Elsevier.

for the rock mantle. It is widely believed that a large part of the ice shell may actually be liquid allowing for an internal ocean. This is suggested by the results of the Galileo mission magnetic field measurements that indicate a field induced by Europa's motion in the magnetic field of Jupiter. Moreover, model calculations show that tidal dissipation in the ice may produce enough heat to keep an ocean underneath an ice lid a few tens of kilometers thick. It is also possible, depending on little known values of *rheology* parameters and thermal conductivity, that radioactive decay and tidal heating in the rock mantle may keep the ocean fluid (**Chapter 10.18**).

Ganymede has an ice shell about 800 km thick, a 900 km thick rock mantle shell, and a metallic core with about the same radius. The case for an iron-rich core is particularly appealing for Ganymede because the magnetometers on Galileo have detected a self-generated field on this satellite (see **Chapter 10.06**). The intrinsic magnetic field of Ganymede is most likely generated in an iron-rich core. The magnetic field data also suggest an induced component although the evidence for the induced field is much less strong. If the latter interpretation is correct, then Ganymede may also have an ocean of perhaps 100 km thickness at a depth of around 150 km. Since tidal heating is negligible at present, the heat that keeps the ocean molten must either be derived from radioactive decay in the rock mantle or from heat stored in the deep interior during earlier periods of strong tidal heating or even from accretion. In any case, the existence of the self-generated field is evidence enough for a molten core or, at least, a molten core shell.

Callisto is unusual among the Galilean satellites because the gravity data suggest that its interior is not completely differentiated. It is likely that there is an ice shell a few 100 km thick overlying a mixed interior of ice and rock also containing iron. It appears as if Callisto has traveled an evolutionary path different from that of Ganymede. The layering may have formed as a consequence of the slow unmixing of the ice and rock/iron components (Nagel et al., 2004). The model requires that Callisto has never been heated above the melting temperature of the ice. It is possible if not likely that the iron is no longer present in its metallic form but is oxidized to form magnetite and fayalite. The oxidation of the iron, if it occurred, would have precluded the formation of a metallic iron core. As for Europa and Ganymede, the magnetic field data suggest an induced field and an ocean for Callisto as well. Since Callisto is not in the Laplace resonance, tidal heating can be discarded as a heat source. The Cassini gravity data for the largest Saturnian satellite Titan suggest that it too is incompletely differentiated, thereby resembling Callisto, a satellite, the surface of which is so different.

The terrestrial planets (**Figure 11**) have ice in only modest concentrations and mostly consist of the rock/iron component. The rock/iron component in these planets, just as in Io, Europa, and Ganymede, is differentiated into a mostly iron core, a silicate rock mantle, and a crust consisting of the low-melting point components of rock (**Chapter 10.02**). The crust, a layer of some tens of kilometer thickness, forms by partial melting of the mantle and melt separation from the mantle. Crustal rock is still being produced on Earth by volcanic activity, but volcanic activity has mostly ceased early on Mars and Mercury (compare **Chapters 10.02**, **10.08**, and **10.09** and Toplis et al. (2013) for discussions on Mars).

Seismology has provided us with a detailed image of the interior structure of the Earth. It is expected that future missions will provide us with similar data for the other terrestrial planets (see **Chapter 10.03**). The most likely candidate here is Mars and the Moon, for which mission scenarios with seismological networks have been repeatedly studied. The seismological data for the Earth show that there are phase transformations mostly at moderate pressures and depths and chemical discontinuities. The existence of these layers and their thicknesses and depths will vary among the planets. For instance, it is likely that Mercury's mantle will not have major phase-change layers simply because the pressure in this small planet does not reach the levels that it reaches within the Earth, but it may be chemically layered as is the Moon. Although the latter is even smaller than Mercury, the seismic data available suggest a layered structure.

The case of the Moon illustrates the importance of data archiving. Only recent progress in seismology has provided the tools to more fully exploit the Apollo data and has demonstrated the layering of the lunar interior including a liquid outer and a solid inner core (Weber et al., 2011). The layering of even small bodies may be due to the very early evolution of the planets. There is evidence that the planets were once covered by what is called a magma ocean, rock molten by the dissipation of the energies of infalling planetesimals during the late stages of accretion. The Moon possibly became chemically layered as the magma ocean fractionally crystallized. The Earth may have escaped that layering because vigorous convection mixed the products of fractional crystallization. The vigor of convection depends on the size of the body or layer undergoing convection.

10.01.6 Surfaces and Atmospheres

The surfaces of most planets and major satellites have been observed optically, in the visible wavelength range of the electromagnetic spectrum, by cameras onboard spacecraft. The gaseous giant planets and subgiants show the top layers of their cloudy atmospheres. Since these bodies lack solid surfaces, their surface radius has been defined to be the radius at which the atmospheric pressure is 10^5 Pa. Mercury and the major satellites except Titan show their solid surfaces. These bodies are lacking substantial atmospheres. The ability of a planet or satellite to keep an atmosphere depends on the planet's gravity (compare **Chapter 10.13**). Equating the kinetic energy of a molecule to its potential energy defines the escape velocity that is independent of the mass of the particle. Atoms, ions, or molecules move at their thermal speed – which obeys a Maxwell–Boltzmann distribution and is proportional to the square root of the ratio of the temperature to the particle mass – but can be accelerated by other processes much beyond their thermal speeds. Among these processes are impacts, photoionization, and pickup by the solar wind, hydrodynamic effects, and sputtering. The presence of a magnetic field will help to keep an atmosphere by blocking the solar wind from eroding the atmosphere. Escape due to the thermal speed (at the long end of the Maxwell–Boltzmann distribution) exceeding the escape velocity is called the Jeans escape and is most relevant for light species such as hydrogen and helium. The Jeans escape can be used for a systematic discussion in terms of planetary mass, radius, and temperature. It explains why Mercury with its comparatively small mass and high surface temperature is prone to losing an atmosphere and why massive Jupiter can bind hydrogen and helium, but it cannot explain why Titan has a substantial atmosphere, while Ganymede, similar in mass, radius, and temperature, has none. The difference may lie with Titan being rich in ammonia from which the mostly nitrogen atmosphere may have formed by photodissociation (Coustenis and Taylor, 1999 and **Chapter 10.18**). It is also possible that the difference between Titan and Ganymede lies with their early differentiation and outgassing histories. The compositions of the atmospheres of the terrestrial planets suggest that any solar-type primordial atmosphere has been replaced by a secondary atmosphere that is the result of outgassing and perhaps cometary impacts (e.g., Pepin, 2006).

The surface temperatures of the planets are mostly determined by the solar radiation and therefore decrease with increasing distance from the Sun. The actual surface temperature will depend on the reflectivity or *albedo* in the visible wavelength of the electromagnetic spectrum, on the emissivity in the infrared, and on the thermal and optical properties of the atmosphere. A useful quantity, the *effective temperature*, can be calculated assuming thermal equilibrium of the surface with the solar radiation neglecting the effects of the atmosphere. The effective temperature decreases from 445 K at Mercury to 50 K for Neptune (**Table 1**). In case of an atmosphere, the energy balance is more complicated (**Chapter 10.13**). Visible light passes through the atmosphere and reaches the surface where it is in part reflected and in part absorbed and reradiated. The infrared radiation emanating from the surface is in part absorbed by CO_2 and/or H_2O in the atmosphere and raises the atmosphere temperature. This effect, the so-called greenhouse effect, is particularly important for Venus (see also Bengtson et al. (2013)) due to the large amount of CO_2 in its atmosphere. (Other minor constituents contribute to the greenhouse effect.) Here, the surface temperature is about 740 K, about twice the value of the effective temperature. It is possible that Mars had a much denser atmosphere in its early evolution that allowed for higher temperatures through the greenhouse effect and liquid water. This would have helped to develop life on this planet (**Chapter 10.14**).

The solid surface of the Earth is partly covered by clouds in the atmosphere and partly visible depending on the extent and the pattern of the cloud cover. Venus' surface, however, is entirely covered by an optically dense atmosphere and the same is true for the Saturnian satellite Titan. Venus' atmosphere is mostly CO_2 and the atmospheric pressure is 9.2 MPa. The pressure at the bottom of Titan's atmosphere is 150 kPa. The orange-colored haze that hides Titan's surface from view is most likely smog produced by the photodissociation of methane. Venus' surface has been explored by radar observation. Titan is also explored by radar through the Cassini mission, which, at the time of this writing, is orbiting the planet and has repeatedly flown past Titan at a distance of about 1000 km. Radar and infrared mapping data have revealed a variety of morphological surface features such as lakes, dunes, and perhaps ice volcanoes suggesting a complex story of climate, geology, and atmosphere/surface interactions (e.g., Jaumann et al., 2009). On 14 January 2005, the European Huygens probe onboard Cassini successfully landed on Titan and returned the first images from its surface. The images reveal a complex surface morphology and suggest rivers and perhaps oceans (**Figure 12**).

The surface of Mars is visible most of the time. The main component of the Martian atmosphere is CO_2 but the atmospheric pressure is much smaller than Venus', of the order of 600 Pa. However, the surface may be hidden during times of global dust storms, which occur repeatedly on the timescales of a few years. Ancient river beds, outflow channels, and erosion features have been taken as evidence that the Martian atmosphere was more massive in the past and the climate was wetter and warmer (see **Chapter 10.11** for a discussion of water and ice on terrestrial planetary surfaces, in particular on Mars, and **Chapter 10.12** for a discussion of atmosphere–surface interactions). However, this view is debated and

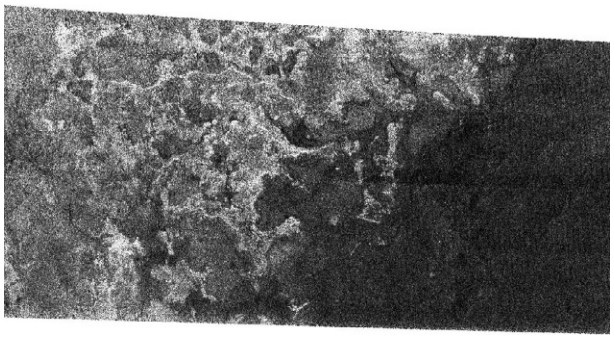

Figure 12 Synthetic aperture radar image of the surface of Titan. The bright, rough region on the left side of the image seems to be topographically high terrain that is cut by channels and bays. The boundary of the bright (rough) region and the dark (smooth) region appears to be a shoreline. The patterns in the dark area indicate that it may once have been flooded, with the liquid having at least partially receded. The image is 175 km high and 330 km wide and is located at 66 degrees south latitude, 356 degrees west longitude in the southern hemisphere of Titan.

alternative scenarios are discussed (**Chapter 10.11**). The findings of the Mars Exploration and Curiosity rovers clearly show that standing bodies of water on Mars were once present in which water-bearing minerals like jarosite precipitated. Water is a prerequisite for a planet to be habitable.

The pressure on Mars is close to the triple-point pressure of water (611 Pa). Thus, there is little room for liquid water except for low-lying regions such as the bottom of impact basins like Argyre and Hellas. However, melt water may exist for some time metastably on Mars and longer as its surface freezes over and it is covered by ice (see also articles in Tokano (2005) and references therein). The widely accepted early disappearance of the magnetic field of Mars (see Schubert et al. (2000) for a dissenting view) may have been partly responsible for the escape of the early Martian atmosphere (see Dehant et al. (2007) for a recent review).

The atmosphere of the Earth differs from those of its neighbors. The atmospheric pressure of 0.1 MPa is in between that of the latter two, and the main components are N_2, O_2, and H_2O.

The outer surface of Uranus is bland, greenish in color, and mostly featureless. The greenish color is attributed to methane and high-altitude photochemical smog. At the other extreme is Jupiter, whose surface features a large number of bands or stripes largely parallel to the equator interspersed with spots and vortices. Particularly remarkable is the giant red spot, a vortex that covers about 1/10 of the planetary disk (see **Figure 1**). These features point to a highly dynamic atmosphere. The dynamics is dominated by the rotation as witnessed by the band structure, but the vortices and spots show that these become unstable at various scale lengths. The brownish to reddish color of some of the features is attributed to ammonium hydrogen sulfide (NH_4SH), while the whitish colors are attributed to ammonium. Saturn's atmosphere is much calmer than Jupiter's, as the surface patterns suggest. These patterns are stripes similar to those in the Jovian atmosphere, but the spots and vortices are missing although wind speeds are extremely high. Neptune is similar to Uranus in that its surface is bluish in color, which is attributed to methane. It resembles Saturn in its stripe pattern. But in addition, there are a few vortices and a large spot that resemble features on Jupiter (the atmosphere dynamics of the giant planets is discussed in **Chapter 10.16**).

The solid surfaces of the terrestrial planets have some common features. Most prominent among these are craters that occur on a very wide range of sizes (compare **Chapter 10.10**). Craters are believed to be remnants of the early evolution of the planets and satellites when the young surfaces were bombarded by planetesimals during the late stage of the accretion process. This phase is often termed the phase of heavy bombardment. The distribution and density of craters on planetary surfaces are an important indication of the age of the surface or parts thereof. The older a surface is, the higher the density of impact craters. For instance, Mars shows a dichotomy in surface age (and topography) between its northern lowland and southern highland hemispheres (see **Figure 8**). The age difference on average is about 1 billion years. Some of the most cratered and therefore oldest surfaces in the solar system are found on Mercury, the Earth's Moon, and the Jovian satellite Callisto. There are surfaces that are saturated with craters, implying that for every new crater formed by an impact, one existing crater will be – on average – destroyed. Geologists and planetary scientists use the term 'exogenic dynamics' to characterize the processes modifying the surface by impacts. Many impact craters on terrestrial planets with atmospheres have been partly or completely destroyed by erosion. Some have been buried by extensive resurfacing in the early history of the planet. On icy satellites, long-term relaxation of the ice may cause craters to flatten out.

Planetary surfaces are also modified by erosion (**Chapter 10.12**) and by processes related to 'endogenic dynamics,' that is, by processes that originate from within the planet (see **Chapters 10.08** and **10.09**). The most prominent of the latter processes is volcanism. Volcanism has shaped at least parts of the surfaces of the terrestrial planets, and silicate volcanism is the one important element of crustal growth. Prominent volcanic features are the giant Tharsis dome on Mars, the island arcs on the Earth, and the Maria on the Moon. The surface of Venus is dotted with volcanoes and plains. As we will discuss further in the succeeding text, endogenic activity scales with the mass of a planet. This partly explains why the activity on smaller planets usually dies off earlier than on the larger planets.

A special case is the Jovian satellite Io (see **Chapter 10.08** and articles in Spencer and Lopes (2006)). This satellite is similar in mass to the Moon, yet it is the most volcanically active planetary body in the solar system. Volcanic features cover its surface but impact craters have not been detected. This shows that the surface is very young and is permanently renewed. The surface is to a large extent covered by allotropes of sulfur and by sulfur dioxide. These deposits cause the yellow to whitish color of the surface. The dark spots are likely volcanic vents and sulfur lakes. Sulfur deposits are often found associated with volcanic structures on the Earth. The high surface temperatures of up to 1600 K indeed suggest silicate volcanism. The reason for the unusual activity on Io lies with an unusual heat source: Io is flexed by tides raised by its massive primary Jupiter. The deformation energy that is dissipated as heat is sufficient to make it more volcanically active

than the largest terrestrial planet, the Earth. A further measure of the enormous energy that is dissipated in Io's interior is the surface heat flow of 2–3 W m^{-2}, 20–30 times larger than the surface heat flow of the Earth. Io's heat flow is rivaled only by Jupiter, which radiates about 5.4 Wm^{-2}. The heat flow through the southern polar cap of Enceladus is also exceptionally high, however (**Figure 13**).

The Earth features a style of endogenic activity, plate tectonics, that, according to our present knowledge, is unique to the Earth (chapters in Volumes 6 and 7 and **Chapters 10.08** and **10.09**). Plate tectonics involves the continuous production of basaltic crust along volcanically active linear ridges at the bottom of the oceans. Prominent examples are the Mid-Atlantic Ridge and the East Pacific Rise. It also involves subduction of this crust underneath island arcs and continental margins. Prominent examples are the islands of Japan for the former and the western continental margin of South America for the latter. These subduction zones are the loci of most of the seismic activity of the planet. Both processes cause the Earth's surface to be divided into seven major plates that drift across the surface. Plate tectonics is driven by extremely slowly circulating convection currents in its deep interior. Although convection is not unique to the Earth but is expected to occur in the silicate rock shells of the other terrestrial planets as well, this feature is usually hidden underneath a thick stagnant lid (see **Section 10.01.7** and **Chapters 10.08** and **10.09**). The reason why convection in the Earth extends to the surface and includes the crust at the bottom of the oceans is not entirely known. It is speculated that this is caused by the presence of water and there may even be links between plate tectonics and life (e.g., Höning et al., 2014; Sleep et al., 2012). In any case, plate tectonics causes the surface of the ocean basins to be completely renewed on a timescale of a few hundred million years. Plate tectonics together with erosion even incorporates recycling of the more stable continents. Material denudated by erosion from the continents is transported to the ocean basins where it is incorporated into the plate tectonics cycle. That loss of continental material is balanced by the production of continental rock through volcanic activity. The cycling of material between the interior and the atmosphere is an important element of the carbon silicate and other elemental cycles that help stabilize the climate of the planet (cf. **Chapter 10.13**). It has been speculated that Mars and Venus went through phases of plate tectonics very early in their histories (see **Chapters 10.08** and **10.09**). However, while this is a possibility, it remains a speculation. Although plate tectonics seems to be unique to the Earth, there are other processes of crust recycling. These involve subcrustal erosion as is assumed for, for example, Io and the foundering of the surface as has been speculated to have happened on Venus at the sites of some coronae Ghail (2002) even proposed a mechanism of "buouyant plate tectonics" for present day Venus.

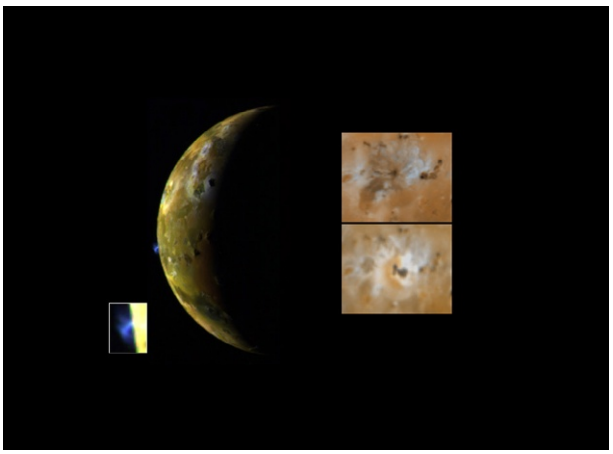

Figure 13 Volcanic plume on Io imaged by the Galileo spacecraft. The blue-colored plume extends to about 100 km above the surface. The blue color is consistent with the presence of sulfur dioxide gas and sulfur dioxide snow condensing as the volcanic gas in the plume expands and cools. The images on the right show a comparison of changes seen near the volcano Ra Patera since Voyager in 1979 (top) and Galileo in 2001 (bottom). An area of 40 000 km^2 was newly covered with volcanic material between the two observations. NASA/JPL.

The best studied example of a single-plate planet is Mars. Three instruments on board spacecraft have recently allowed major progress for detailed studies of the tectonics of this planet (**Chapter 10.09**). The first is the laser altimeter MOLA on Mars Global Surveyor, the second is the HRSC camera on Mars Express, and the third is the HiRISE camera on the Mars Reconnaissance Orbiter. While MOLA has stopped operating as an altimeter in 2001 after covering the entire surface due to the finite lifetime of its laser pump diodes, HRSC has covered almost the entire planet at a resolution of 10 m px^{-1} at the time of this writing and HiRISE has supplemented this data set with images down to 30 cm px^{-1}. One major achievement by these instruments is the establishment of an accurate geodetic network of surface features.

The topography of Mars exhibits a clear dichotomy that divides the surface into a southern highland hemisphere as heavily cratered as the lunar highlands and rising several thousands of meters above the zero level and a northern lowland hemisphere that lies well below the datum. The origin of the dichotomy is ascribed variously either to long-wavelength mantle convection, to impacts, to postaccretional core formation sweeping up most of the crustal material into one large protocontinental mass, or to combinations thereof (see discussion in **Chapters 10.08** and **10.09**). The highlands cover about 60% of the planet, including almost all of the southern hemisphere. The surface has survived since the heavy bombardment prior to 3.8 billion years ago with only minor modifications and thus records the early history of the planet.

Venus whose surface has been mapped by the Magellan and Venus Express missions with radar and in the infrared is another well-studied single-plate planet. Its hypsometric curve, however, has a single peak rather than having double peaks as those of Mars' and the Earth's curve. Venus has no distinct volcanic center such as Mars but a prominent rift system, the Beta, Atla, and Themis Regiones. Volcanic features include a large number of comparatively small shield volcanoes that are apparently randomly distributed, volcanic plains, and about 500 coronae – circular large-scale volcanotectonic features. It is widely accepted that most coronae form above upwelling plumes (Smrekar and Stofan, 1999). The comparative paucity of impact craters on the surface has been used to suggest that Venus was resurfaced about 500–700 million years ago by a volcanic event of global scale (Schaber et al., 1992;

McKinnon et al., 1997). This event was followed – as the model suggests – by almost no volcanic activity. The early conclusions from the cratering record have been challenged by, for example, Hauck et al. (1998) and Campbell (1999). According to these authors, the cratering record allows a variety of interpretations in terms of volcanic resurfacing including a global decrease in time in the rate of volcanic activity.

10.01.7 Energy Balance and Evolution

Although the evolution of the planets seems to have followed some common general lines, there are significant differences among individual planets. The evolution of the terrestrial planets and moons is discussed in **Chapter 10.08** and of the icy satellites in **Chapter 10.18**. The evolution of the giant planets is discussed in **Chapter 10.16**. The early evolution of all planets has been dominated by impacts from the debris left over from planet formation (**Chapter 10.10**). Moreover, isotopic evidence suggests that the planets differentiated by iron-core formation early within a few tens of million years (e.g., Kleine et al., 2002). Of course, the evidence for Mars rests with the very well-founded assumption that the so-called SNC meteorites are in fact rocks from Mars. It is further believed that the planets started hot, heated by the energy deposited in the interior during accretion and by heat dissipated upon differentiation – the terrestrial planets heated to near-melting temperatures of their rock components and to temperatures well above the iron-melting temperatures. The planets then cooled from this initial hot state and the cooling drove their evolution. It is possible, for instance, to explain the present rate of infrared radiation from Jupiter simply by cooling. This is not possible for Saturn, for which an additional heat source is required. The continuing gravitational settling of helium may provide enough energy to explain the observed present luminosity of this planet. The energy balances of most other planets and satellites seem to invoke both cooling and heat generated by the decay of radioactive elements, in particular of uranium, thorium, and potassium (the isotope ^{40}K), which generates 4–5 pW kg^{-1} of rock. A further possibility is tidal heating, but this mechanism seems to be relevant at present only for Io and, perhaps, Europa and Enceladus.

It should be stressed that the energy balances of the planets are not very well known. A crucial quantity, the surface heat flow – or the intrinsic luminosity – is known for the giant planets, which radiate enough energy in comparison with the solar insolation incident on their surface that their luminosity can be measured from orbit. This is also true for the heat flow from the volcanic hot spots on Io, but there is a major uncertainty concerning the flow through the remainder of the surface. Nevertheless, the enormous luminosity of this satellite of at least 1.5 W m^{-2} is remarkable. Another remarkable value is the roughly 6 GW (Spencer et al., 2006) radiated from the southern hemisphere of Enceladus. On the terrestrial planets and the other satellites, as far as we know them today, the surface heat flow must be measured *in situ* (compare **Chapter 6.05** by Jaupart). This measurement requires a borehole deep enough to avoid the influence of the daily and seasonal temperature variations of the atmosphere. This difficult measurement has been done at many locations on the Earth and at two sites on the Moon. The InSight mission scheduled for launch to Mars in 2016 will attempt a surface heat flow measurement. In **Table 1**, we list the specific luminosities or surface heat flows for the planets and satellites for which the heat flows and luminosities have been measured. Since heat production depends on mass, we have divided the heat flows by the masses. A comparison of the entries in **Table 1** shows that the Earth and the Moon are within a factor of two of the specific radioactive heat production rate of rock suggesting that about half of the heat flow can be attributed to cooling and half to heat production. This conclusion is known to hold for the Earth even on the basis of more specific data and more careful energy balances (compare **Chapters 9.08** and **9.09**). An educated prediction of the heat flows for Mars, the other terrestrial planets, and the major satellites could be based on the aforementioned observation. The specific luminosity of Uranus also is close to the radiogenic heat production rate per unit mass of rock given in the preceding text. It is likely that Uranus has a substantial rock core in which that heat is generated.

Neptune, Io, and Europa stand out in comparison with the terrestrial planets. In the case of Neptune, the extra heat flow has been attributed to cooling and whole-planetary contraction. For Io, the extraordinary large heat flow is with little doubt due to tidal heating although ohmic dissipation of energy carried by electric currents between Io and Jupiter is sometimes quoted. The value for Europa in **Table 1** is highly uncertain and has been derived from indirect observation of tectonic surface features (e.g., Ruiz, 2005). If the estimate were correct, then tidal heating would be the best explanation for its value. However, equilibrium models of tidal heating arrive at values smaller by about one order of magnitude (cf. **Chapter 10.18**).

The dynamic or geologic, chemical, and magnetic evolutions of the planets are mainly governed by their thermal evolution. Planets can be regarded as heat engines that convert heat into mechanical work and magnetic field energy. Mechanical work will be performed by the building of volcanic structures and mountain belts, for example, or during the movement of plates over the Earth's surface (cf. Volumes 6 and 7). The agent for these processes is convective heat transport, a mode of heat transport that involves movement of hot material to cold surfaces and cold material to hot surfaces (see, e.g., Schubert et al. (2001) and **Chapter 7.02**). Convection is driven by sufficiently great temperature differences across a layer or planetary shell and occurs if the layer is unstable against convective overturn. Convection is possible even in the solid rock mantles of the planets because of the long timescales that are involved. On geologic timescales of tens to hundreds of millions of years, rock behaves as a very viscous fluid. The convection flows at speeds of centimeters per year still transfer more heat than conduction. This is in part due to the enormous masses involved in the flow and in part due to the very low thermal conductivity of rock. There is even a thermostat principle at work in the silicate and ice shells (the Tozer principle) (Tozer (1967)) since the viscosities of these solids are strongly temperature-dependent: If the flow is too

slow to transport the heat, the temperature will increase until the flow is strong enough to transfer the heat. If the temperature is so high such that the convective heat transfer rate largely outbalances the heat production rate or the heat flow into the layer from below, then the temperature will decrease, viscosity will increase, and convective vigor will decrease. Convection is extensively discussed in Volume 7. The thermal evolution of the Earth is discussed in Volume 9. Chemical differentiation is mostly a consequence of melting and the density difference between melt and solid that will again lead to movement. A particularly good example for the chemical differentiation of the terrestrial planets that occurs in addition to core formation is the growth of the crust through volcanic activity (see Chapter 10.08). However, secondary crustal growth likely involves much longer timescales than core formation.

The material in the crust is derived from partial melting of the mantle. Partial melting is possible when a material of complex chemistry lacks a simple melting temperature. Rather, in materials such as rock (and ice of complex chemistry), there will be a temperature termed the solidus temperature at which the material begins to melt. The melt will consist of that component of the entire assemblage that has the lowest individual melting point. The remaining solid will be depleted in that component. As the temperature rises, other components begin to melt until, finally, at the liquidus temperature, the whole assemblage will be molten. In the rock component of planets, the component to most easily melt is basalt. Once a basalt liquid forms in the interior of a planet, it will tend to rise to the surface by virtue of its lower density than the density of the remaining rock. In a water–ammonium ice, the low-melting component will be a water–ammonium mixture of a particular composition. In most cases, the melt is likely to be produced within the top few 100 km of a planet by a process termed pressure-release melting. Pressure-release melting occurs when the melting point gradient is steeper than the average temperature gradient. Relatively hot uprising convection currents will emanate from depths where the temperature is below the melting temperature. Upon rising to the surface adiabatically (i.e., with no or little heat exchange), the flow will hit a depth where the solidus temperature is exceeded and partial melting will ensue. Because melt is usually much more compressible than solid, there will be a pressure and a depth below which melt will no longer be buoyant to rise to the surface but may actually sink towards the deeper interior. Melting in the interior of planets requires a heat source. This source is mainly the heat that is stored in the planets during accretion and the heat that is generated by the decay of radiogenic elements. Both are finite reservoirs that will not be replenished. That is why endogenic activity decreases with time.

Since melting occurs when hot material from the deep interior rises in convection currents, the surface distribution of volcanism is speculated to give an indication of the planform of the convection underneath. The timing of the volcanic activity can be used as a guide for assessing the time evolution of the convection. For instance, the differing surfaces of Mars and Venus may have recorded differing planforms of mantle convection and flow history. The dominance of Tharsis on Mars (compare Figure 8) suggests that there is or that there once was a giant superplume, a very large upwelling underneath this volcanic dome. The geologic evidence suggests that Tharsis formed early but that volcanic activity has been ongoing to the recent past (cf. Chapter 10.08). This long-term stability of Tharsis as the major center of volcanic activity on Mars is puzzling, the more so since model calculations suggest that the superplume's lifetime should be not much more than one billion years. Although Tharsis apparently formed early, the photogeologic evidence also suggests that volcanic activity on Mars started globally and retreated to Tharsis over time and may then have decreased in vigor. On Venus, there is an indication that the volcanic activity has been global even recently (on geologic timescales, recently involves the past 10–100 million years). There is further (albeit debated) evidence for a global volcanic resurfacing event a few hundred million years ago. This suggests that the thermal history of a planet may have involved episodes of more and of less activity that most likely were linked to episodes of greater and less vigor of convection. Volcanism may also have influences on a hydrosphere and atmosphere by degassing the deep interior of volatile elements. At the time of strong volcanism, an increase of atmospheric gases or water on the planet's surface is expected.

There is a fundamental difference between the evolutions of the Earth and most other terrestrial planets and major satellites that is related to the occurrence of plate tectonics on the Earth (discussed in Chapters 10.08 and 10.09). Since the viscosity or, more generally, the rheology of rock is strongly temperature-dependent and since the surface temperatures of these planets are much lower than the melting temperatures, it follows that there must be outer layers that are comparatively stiff. These layers are termed the lithospheres. Usually, the lithospheres are connected lids that are pierced here and there by volcanic vents. Convection currents flow underneath the lithosphere and deliver heat to the base of the lid through which it is then transferred to the surface by heat conduction. Since these lids are stagnant, this form of tectonics is often termed stagnant-lid tectonics. On Earth, however, the lithosphere is broken into seven major plates that move relative to each other driven by the convective flow underneath. Volcanic activity occurs along some plate margins and results in the growth of plates. Other plate margins are destructive and are loci where plates are forced under their own weight to subduct into the mantle. There is no convincing evidence that plate tectonics occurs on any other planet or satellite although it has been speculated that it may have occurred on early Mars and on the Jovian satellites Europa and Ganymede. There is evidence in the images of the surface units of lateral movement on these two satellites. The Jovian satellite Io does not seem to be undergoing plate tectonics. However, its present resurfacing rate, which is larger than the resurfacing rate of Earth, calls for some recycling of Io's crust volcanic material with the underlying mantle. This recycling probably occurs through delamination of the base of the crust. Delamination of the base of the crust may have been or may be operative on other planets such as Venus (Figures 14 and 15).

The interior evolution of the gaseous planets is even less well constrained. It must be assumed that the dynamics of their atmospheres is related to the vigor of convection underneath, but the solar insolation also matters. Thus, models of the evolution are mostly constrained by their luminosities, but as we have seen in the preceding text, these leave enough puzzles

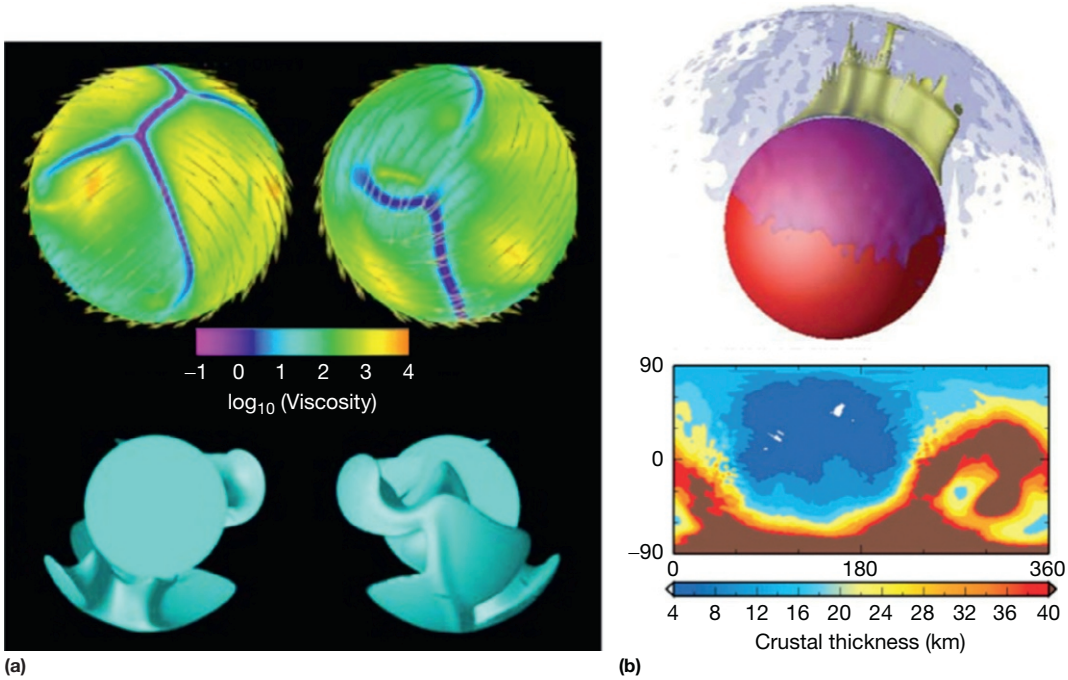

Figure 14 (a) Numerical simulations of mantle convection with plate tectonics in a three-dimensional spherical shell. The top line shows two views of the viscosity field at the surface. Rigid plates moving with uniform velocity are separated by both divergent and convergent narrow boundaries with low viscosity at which plates form and are recycled into the mantle. The bottom line shows temperature isosurfaces representing the subduction of cold downwellings (after van Heck H and Tackley PJ (2008) Planforms of self-consistently generated plate tectonics in 3-D spherical geometry. *Geophysical Research Letters* 35: L19312, http://dx.doi.org/10.1029/2008GL035190). (b) Numerical simulation of the formation of Mars' crustal dichotomy by mantle convection. The top panel shows a hot upwelling plume (yellow) rising from the core–mantle boundary (red) able to generate a large region of partial melt (light blue). Migration of the melt towards the surface leads to the formation of a crust (**Section 10.01.7**) whose thickness in the southern hemisphere is much greater than in the northern one (bottom panel) (after Šramek O and Zhong S (2012) Martian crustal dichotomy and Tharsis formation by partial melting coupled to early plume migration. *Journal of Geophysical Research* 117(E01005), http://dx.doi.org/10.1029/2011JE003867).

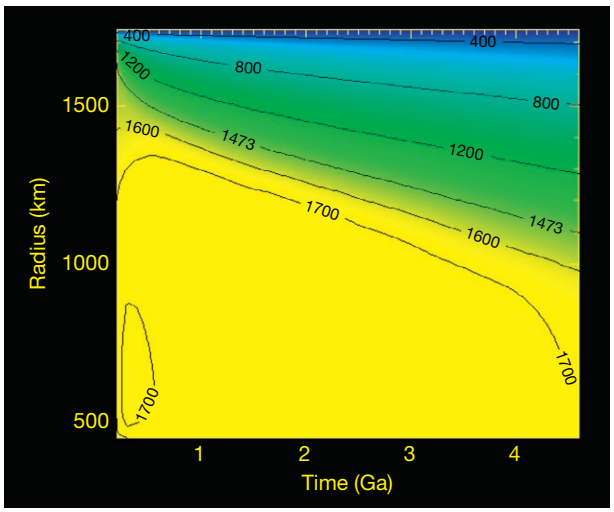

Figure 15 Growth of a stagnant lid in the lunar mantle. The growth of a cold, thermally conductive lid on top of the lunar mantle is shown as resulted from convection model calculations by Konrad and Spohn (1997).

to be solved as witnessed by the differences between the luminosities of Neptune and Uranus.

10.01.8 Magnetic Fields and Field Generation

Mercury, Earth, and the giant planets have largely dipolar magnetic fields that are produced by dynamo action in their interiors. Of the major satellites, only Ganymede is known to produce a magnetic field. The Galileo and Cassini data suggest that neither the other Galilean satellites of Jupiter – in particular not dynamic Io – nor the big Saturnian satellite Titan have self-generated fields. The magnetic fields of these planets and moons are described and discussed in **Chapter 10.06**. The physics of planetary dynamos is discussed in **Chapter 10.07**. **Chapter 10.08** discusses the generation of the magnetic fields of terrestrial planets in the context of their thermal evolution, and **Chapter 10.16** the generation of magnetic fields in the giant planets. **Chapter 10.18**, finally, discusses the magnetic fields of outer solar system satellites. Planetary magnetism is also extensively reviewed and discussed in Christensen et al. (2011).

The icy Jovian satellites Europa, Ganymede, and Callisto are surrounded by magnetic fields that vary along with their movement through the magnetosphere of Jupiter. These fields are, therefore, interpreted to be induced in electrically conducting layers in the satellites' interiors as the satellites orbit Jupiter and are subject to a time-varying magnetic flux. The geometry and the strengths of these fields suggest that the conducting layers are at depths of some tens to a few hundred kilometers and are most likely salty oceans. No evidence for an induced field at Titan has been reported. Thermal considerations suggest that these oceans are feasible (**Chapter 10.18**). Ganymede is agreed to have an induced field on top of its permanent magnetic field.

Self-sustained magnetic fields are generally thought to be enigmatic to planets, part of their interior evolution during which thermal (and potential energy) is converted into mechanical work and magnetic field energy. The Mars Global Surveyor data have confirmed this hypothesis by showing that Mars has a remanently magnetized crust. This crust must have been magnetized during an epoch when Mars was generating its own magnetic field. Interestingly, it is mostly the oldest crust units that are magnetized. It has long been speculated that Mars, Venus, and the Earth's Moon once produced magnetic fields by dynamo action in their cores (e.g., Stevenson et al., 1983). The observation of magnetized rock on the surface of Mars now confirms this general notion (**Figure 16**).

The dynamo mechanism (e.g., **Chapter 10.07** but see also **Chapters 10.08** and **10.16** and chapters in Volume 8, in particular **Chapter 8.03**) invoked to explain magnetic field generation is similar among the planets although the source regions differ between the terrestrial planets and major satellites, the giant planets, and the subgiants or ice giants, Uranus and Neptune. Required is an electrically conducting and fluid region that undergoes turbulent flow driven by thermal or compositional buoyancy. If a magnetic field exists, for instance, the external magnetic field of the Sun or a primary planet, a field will be induced in the source region. The flow will distort the field lines and thereby generate magnetic field energy by induction. If the flow satisfies certain conditions, the interference between the generated field and the preexisting field can be constructive, powering and maintaining a magnetic field against dissipative losses.

For the terrestrial planets and the major satellites, the candidate source regions are the fluid metallic cores or outer core shells. Because of their low viscosities (around 1 Pa), these regions are often unstable with respect to thermal convection. The stability is generally accepted to depend on the rate of heat removal from the core by the mantle convection flow. If the latter is too low (below about 10 mW m^{-2} but depending on pressure), the heat flow in the mantle can be balanced by heat conduction in the core, and the core will be stably stratified. Dynamo action is then not possible. If the heat flow into the mantle is larger than the critical value, convection in the core must be invoked to balance the heat removal rate. The situation becomes more favorable for convection in the core if the core begins to freeze and to grow a solid inner core. First, latent heat liberated upon inner core growth will help to power the dynamo. Second, the core may contain light alloying elements such as sulfur and/or oxygen. The light alloying elements expelled from the solid inner core can drive (chemical) convection and a dynamo very effectively because this dynamo will not be subject to a Carnot efficiency factor that by the second law of thermodynamics limits the efficiency at which a heat engine can do work. In this model of the chemical dynamo, the melting curve is always steeper than the core (adiabatic) temperature profile. It is believed that the cooling of the core and growth of the inner core drive the Earth's core dynamo.

A new class of chemical dynamos described in **Chapter 10.08** has been discussed in recent years in particular for terrestrial planets and satellites smaller than the Earth. Examples are the Earth's Moon, Ganymede, Mercury, but possibly even Mars.

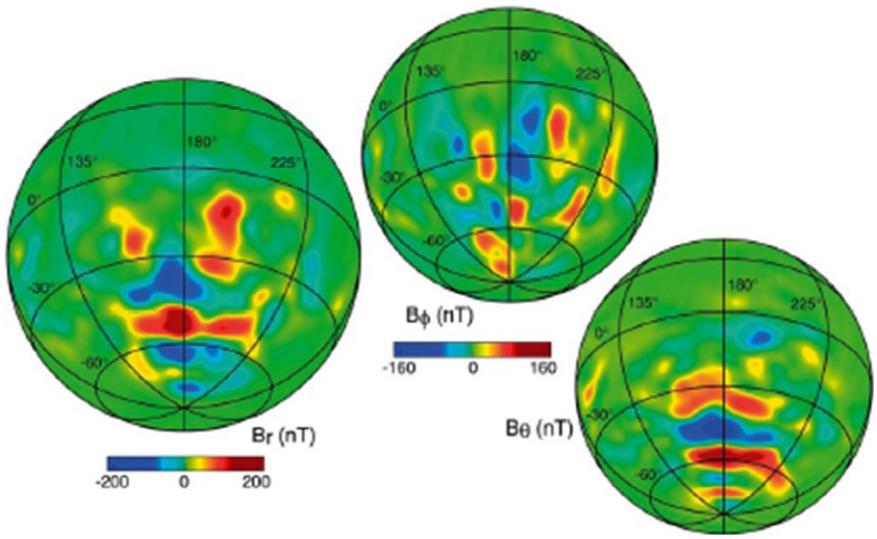

Figure 16 Orthographic projections of the three components of the magnetic field in spherical coordinates (r, radius; Θ, latitude; and Φ, longitude) onto the surface of Mars at a nominal mapping altitude of 400 km. Reproduced from Connerney JEP, Acuna MH, Ness NF, Spohn T, and Schubert G (2004) Mars crustal magnetism. *Space Science Reviews* 111: 1–32.

The new model is based on the observation that the iron-rich core alloy melting relations may be more complicated than in the older models where the application of the Lindeman melting law warranted that the melting was steeper than the adiabat. In particular, it is possible that the melting curve is less steep than the adiabat and the gradient may even be negative. In both cases, the core will not freeze from the center outward, but iron snow will form in the outermost parts of the core. As the iron snow sinks into the core, it will form a partially molten layer in which solid iron and melt are in equilibrium underlain by a layer of melt enriched in iron with respect to the average composition of the core alloy. The latter layer will be gravitationally instable and drive chemical convection and possibly a dynamo. As the core cools, the partial melt layer (with neutral buoyancy) will grow and eventually the dynamo becomes frustrated. The model may be able to explain why the Moon can have a solid inner core at present without generating a magnetic field.

Dynamo action in a terrestrial planet thus depends on the efficiency of mantle convection, on the composition of the core, and on the core material phase diagram. Plate tectonics is very effective at cooling the deep interior of a planet because the cold plates sink deep into the mantle. It is therefore conceivable that the Earth's core has been cooling to temperatures below the liquidus of its core alloy. Venus, a planet of similar size, appears to have been lacking that efficient cooling mechanism and appears to be cooling by convection underneath a stagnant lid. Consequently, the heat flow from the core has become subcritical over time, and the core may have not been cooling enough to reach liquidus temperatures. As a consequence of this and the general decline of mantle convective vigor, the core became stably stratified and a possible early dynamo ceased to operate. A similar scenario is possible for Mars, but the iron snow model may provide an alternative explanation for an early dynamo that ceased to operate. It would be interesting to see whether or not Mars has a solid inner core. There is little hope to find remanently magnetized crust on Venus should landing missions be able to overcome the forbidding operating conditions on this planet. The surface temperature of around 450 °C is above the temperatures at which candidate minerals become remanently magnetized. The Moon has a remanently magnetized crust and may be another good candidate for the iron snow model. Alternative explanations for the recorded remanently magnetized crust units invoke plasma clouds generated by major impacts. Some of the strongest magnetic anomalies (albeit weak in comparison to Mars) are suspiciously located at the antipodes of major impact basins. Mercury differs from both the Moon and Mars because of its extraordinarily large core and thin rocky mantle. The thin mantle should be quite effective, as model calculations suggest, at removing core heat and driving a dynamo that produces a magnetic field, albeit weak. The weakness of the field has been discussed to be difficult to explain with conventional dynamo theory (compare **Chapter 10.07**).

Dynamo action in the gaseous giant planets (**Chapters 10.06**, **10.07**, and **10.16**) most likely happens in the regions where hydrogen becomes metallic due to the extraordinary large pressure. The magnetic fields of these planets are most likely powered by the energy that has been stored in the planets during accretion and that is removed by convection. The transition to metallic hydrogen occurs at a depth of roughly 15 000 km in Jupiter and almost twice as deep in Saturn. The larger depth of dynamo action may partly explain why Saturn's field is much more ideal in terms of a dipole than Jupiter's. In the source regions, the fields are likely to be very complex and not at all similar to a dipolar planetary field. The field in the source region can be thought of as a superposition of many multipolar fields of various amplitudes. Distance from the source region affects the higher-order multipolar fields much more strongly than the lower-order fields. If n is the order ($n=2$ for a dipole), then the strength of the field components decreases with radial distance r from the source regions as r^{-n}. Thus, a planet with a comparatively deep source region should feature a more ideal dipolar field as compared with one where the source region lies less deep. This does not explain entirely the characteristics of the Saturnian magnetic field for which screening by helium rain has been additionally invoked.

The pressure in the interiors of the subgiants Uranus and Neptune is not sufficient to cause a transition to metallic hydrogen. Rather, it is believed that there are ionic oceans at relatively shallow depths in these planets. In these ionic oceans, the magnetic fields can be generated. The fields of the subgiants have been measured only by a single flyby each and are therefore not well known. Nevertheless, it appears that these fields are very complex in their topologies. This fits in nicely with the idea of the fields being generated at relatively shallow depths.

10.01.9 Origin of the Solar System

The origin of the solar system is not covered in this book. The reader is referred to Volume 1 of the Treatise on Geochemistry (Holland and Turekian, 2003). A most recent overview can be found in Chambers and Halliday (2014), and more detailed recent reviews in the Protostars and Planets V (Reipurth et al., 2007) and VI collection of articles (Beuther et al., 2014). The formation of satellites is discussed in **Chapter 10.17**.

The basic elements of the theory of the origin of the solar system are similar to the Kant–Laplace hypothesis of formation from a gaseous nebula, but the details are debated. It is widely accepted that the nebula collapsed to form a central mass concentration – the protosun – surrounded by a spreading thin gaseous disk. The most widely held view postulates that temperature in the inner part of the nebula soon became low enough – about 1500 K – to allow the condensation of silicate and iron grains. In the outer solar system, beyond about 5 AU, temperature became so small as to allow condensation of ice phases. Within the first few million years, these solid grains agglomerated to form bigger grains that, in turn, agglomerated to form even bigger ones. The cascading scenario of ever bigger and fewer planetesimals led to the formation of solid bodies the size and mass of the terrestrial planets in the inner solar system and a few tens of Earth masses in the outer solar system. In the outer solar system, these solid protoplanets became the cores of the giant planets. Growth of the solid protoplanets slowed to almost a standstill as the solid matter became exhausted, at least in the feeding zone of the protoplanets that is determined by the competition between a protoplanet's gravity and the gravitational pull of the Sun. At about one Earth mass, a protoplanet begins to

accrete gas onto its surface. The heat dissipated during the influx of planetesimals was radiated from the surface of the forming gaseous envelope. After the influx of solid matter ceased, the protogiant planets began to cool and to contract, thereby increasing its potential to accrete more gas. The growing mass led to even more accretion and runaway growth was set in place. Runaway accretion came to a halt when a gap formed in the nebula around the planet. This gap can form as a consequence of the competing gravities of the protoplanet and the Sun and as a consequence of the finite viscosity of the gas.

A relatively new feature of solar system formation models is that giant planets can move inward (and outward) through interaction with the nebula, thereby perturbing the orbits of smaller planetesimals and protoplanets. The popular Nice model (named after the city where its basic elements were developed; Gomes et al., 2005; Morbidelli et al., 2005; Tsiganis et al., 2005) includes the effects of resonances between the orbits of the giant planets and offers explanations for the relative small mass of Mars along with late heavy bombardment and the formation of the asteroid belt.

The general model offers an explanation of the grand features of the solar system: The inner planets are solid and of refractory composition because the temperature in the inner nebula favored the condensation of refractory phases. The inner planets are small because the feeding zone was smaller with less mass of solid particles. The bigger of the inner planets – the Earth and Venus – have atmospheres with masses as expected although the present atmospheres are not likely to be the primordial ones, which were lost and replaced by degassing of the interiors. In the outer solar system, we find planets with cores of some ten Earth masses and massive gaseous envelopes. In addition, we find wealths of satellite systems witnessing accretion in orbit around the growing protogiants. There are a number of features that can be explained by fine-tuning the theory, for instance, the differences between Jupiter and Saturn and Uranus and Neptune but this will not change the grand picture.

Giant impacts, a mechanism of great importance for some bodies, are the final events of the accretion scenario. Giant impacts are thought to have caused the formation of the Moon (e.g., Canup, 2004; Galimov and Krivtsov, 2012) and may be responsible for the high density of Mercury. A giant impact is a collision of almost grown protoplanets. For instance, it is thought that the Moon formed after a Mars-sized protoplanet hit the proto-Earth. The outer layers of the Earth vaporized during the impact, and the Moon formed from the condensed vapor cloud. Among the arguments for the giant impact hypothesis for the formation of the Moon is the geochemical closeness of the bulk Moon to the Earth's mantle. Mercury may have suffered a similar giant impact that removed a substantial part of the original planetary mantle (e.g., Benz et al., 2008). This may explain why present Mercury has a comparatively big core and a thin mantle and thus an extraordinary large average density. A Moon did not form around Mercury because of the closeness to the Sun. Giant impacts may also affect the rotation, and it has been proposed that Venus' retrograde rotation may thus be explained. Similar explanations have been brought forward for Uranus.

10.01.10 Concluding Remarks

With this overview, I have tried to take the reader on a tour through the solar system and provide the stage for the detailed articles in the remainder of the volume. The planets are largely of solar composition but differ in their depletion in volatile elements. The degree of depletion increases with decreasing mass and with decreasing distance from the Sun with Jupiter being closest in composition to the Sun and with the terrestrial planets being mostly depleted in volatile elements. The planets are mostly internally differentiated with the heavy elements tending to be found near the center and the most volatile elements near the surface. The gaseous planets present the observer with their top layers of their envelopes, while most of the smaller planets present their solid surfaces. Relicts of very early impacts characterize these surfaces to varying degrees. But these surfaces also reveal the signs of volcanic and tectonic activity and erosion. In general, the smaller the solid-surface planet, the more characterized is its surface by early impacts. The volcanic activity and the magnetic fields of those planets that have self-generated fields are due to convection currents in their interiors driven by cooling and by heat generated by radioactive decay or by the dissipation of tidal energy. The source regions of the magnetic fields are metallic or, in the cases of Uranus and Neptune, ionic fluids. Life has had a chance to develop on Earth but possibly also on Mars and Europa. Finding evidence for life outside Earth is a challenge for the future. The bio–geo system of Earth may be a self-regulating system that sets this planet apart from its sister planets. Its position in the solar system, together with a moderate greenhouse effect in its atmosphere, has provided the planet with habitable temperatures and with an atmospheric pressure allowing for liquid water. Life plays an important role here by removing CO_2 from the atmosphere and moderating the greenhouse effect. Water, on the other hand, may be instrumental for plate tectonics since its effect on the rheology may pave the way for surface plates to subduct to the deep interior, thereby cooling the core. The cooling of the core is speculated to be instrumental for magnetic field generation. The magnetic field is a feature that the Earth's brother and sister planets Mars and Venus lack. The magnetic field protects the environment, and thereby life, from radiation. It will be important to see whether or not life developed in the less friendly environments of Mars or even Europa or early Venus.

The future in scientific planetary exploration on the one hand certainly lies with systematic remote sensing with long-term orbiters. These missions will create data volumes that require either long-term operation and communication or significantly increased data acquisition and transmission rates. On the other hand, *in situ* exploration with rovers and planes and networks of surface stations with long operational lifetimes to observe the atmospheres and the interiors will be important. A further challenge for the future will be the return of samples from planets and small bodies. The sophistication of terrestrial laboratories cannot simply be transferred to other planetary surfaces given the scarcity of resources such as mass and power on spacecraft. The technological challenge remains miniaturization. Although many planetary worlds are forbidding to human exploration and require the operation of robots

(think of Venus), it is probably true that the human explorer cannot be topped in its ability for *in situ* scientific study and operation of hardware.

Closer to home, the challenges for planetary geophysics and planetary science in general lie with numerical modeling and laboratory studies. For instance, the rheology of planetary matter is not sufficiently well understood as are the properties of materials in the deep interiors of the Earth and Venus, let alone Jupiter and the other giant planets. Numerical modeling has advanced largely in step with the advancement of computer power, but for geophysical modeling of, for example, the dynamo and mantle convection, the achievable parameter ranges are still in many cases far from the realistic ones.

Exploration has started to look beyond the solar system for other planetary systems. About two thousand confirmed extrasolar planets have been discovered to date in the mass and radius ranges from 10 Jupiter masses down to Earth size and even Mars size. Of course, interest is directed towards Earth-like planets in the habitable zone around Sun-like stars in other solar systems! These planets are beyond the reach of present observational tools, and space agencies are planning to launch space-based telescopes that will be more capable such as the planned ESA PLATO mission and the NASA TESS mission. Also, the James Webb Space Telescope will provide unprecedented opportunities.

But the questions are the following: Is the Earth typical? May other solar systems have planets with thick ice covers such as the icy moons of Jupiter, but bigger? Is it conceivable that there are planets of about the Earth's size with primordial, Jupiter-like atmospheres (Stevenson, 2004)? From a theoretical point of view, these worlds are possible (a statement that may simply reflect our ignorance). In the icy planets, radiogenic heat may support oceans and it is conceivable that these oceans harbor life. Could life even exist in gaseous envelopes?

10.02.1 Introduction

The inner planets Mercury, Venus, Earth, and Mars and terrestrial-type bodies like the Moon and some of the outer planet satellites are mainly composed of silicate rock and metals like iron. They are characterized by relatively small masses and radii and large densities in comparison with the giant planets of the outer solar system. Measurements of rotation and gravitational and magnetic fields indicate that the interiors of these bodies, like the interior of the Earth, are chemically and rheologically layered and subdivided into iron-rich cores, silicate mantles, and rocky crusts derived from partial melting of the mantles. It is generally believed that the internal differentiation of the terrestrial planets and major satellites took place early in their histories only shortly after accretion from colliding planetesimals (Kleine et al., 2002). Even the asteroid 4 Vesta, an accretional remnant left over from that period, reveals a variegated surface with characteristic spectral features hinting at a strongly differentiated interior (Drake, 2001; Ghosh and Mcsween, 1998; Keil, 2002; Kleine et al., 2002; Righter and Drake, 1996, 1997).

The investigation of planetary interiors is among the most important scientific objectives of interplanetary space missions. The state of knowledge of planetary differentiation provides important clues on the general understanding of the internal structure, thermochemical evolution, and bulk composition of the terrestrial planets and terrestrial-type bodies like the Moon and a number of outer planet satellites. Many large-scale planetary processes are controlled by the internal structure of these bodies. Surface geology and tectonic features are mainly affected by mechanisms that dominate the transport of internal heat from the interior to the surface. The existence of self-sustained and/or induced magnetic fields requires reservoirs of electrically conducting fluids at some depth, providing additional constraints on the present thermal state of these bodies. Since a fluid layer within a planetary body mechanically decouples the deep interior from its outer portion, the propagation of seismic waves, the way in which a planet or satellite responds to tides, and the rotational state in terms of spin-axis precession rate, obliquity, forced libration amplitude, and nutations are strongly affected by the physical state of its interior.

Models of the interior structure of a number of terrestrial-type planetary bodies are shown in **Figure 1**. These models are based on theoretical considerations that are strongly constrained by Earth-based and remote-sensing observations, in situ measurements, and laboratory studies of planetary materials and meteorites. Interior structure models aim at calculating (1) the volumes and masses of major chemical reservoirs (crust, mantle, and core) that contribute to the bulk composition, (2) the depths to chemical and rheological discontinuities and mineral phase boundaries, and (3) depth variations of pressure, temperature, density, and composition. In the absence of seismological data, the most important

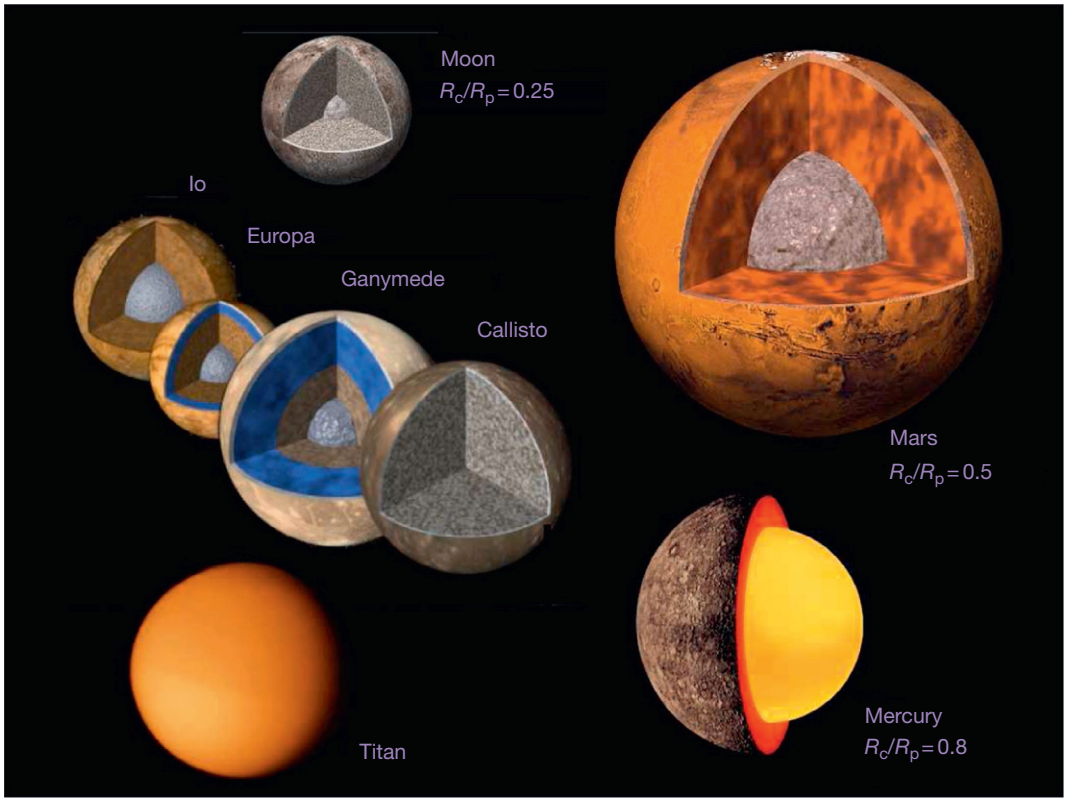

Figure 1 Cutaway views of the interiors of a number of terrestrial-type bodies. R_c/R_p denotes the core radius of a planet or satellite relative to its total radius. parameter that permits a rough estimate of how the interior is composed is the average or mean density.

The mean density is affected by bulk composition, thermal state, self-compression, and pressure-induced mineral phase transitions caused by the weight of overlying layers. In lieu of seismological observations, the determination of the axial moment of inertia (MoI), usually by measurements of the spin-axis precession rate, augmented by low-degree gravity field data and possibly the magnitude of forced libration of the outer solid shell, provides the principal constraint on the concentration of mass toward the center of a planet or satellite. Large-scale gravity and topography data are also important in constraining internal mass distributions since the shapes of the physical surface and the external gravitational field are tied to the radial density distribution and compositionally and/or thermally induced lateral density heterogeneities.

This chapter is arranged as follows: In Section 10.02.2, those observational methods that provide constraints on the interior structure and composition of terrestrial planetary bodies are reviewed. Section 10.02.3 provides the mathematical background for the construction of spherically symmetrical density models and discusses thermodynamic quantities and associated equation-of-state parameters relating ambient material properties to local (pressure and temperature) material properties. Section 10.02.4 describes the interior of the Earth as a type example of a terrestrial planet and is followed by Sections 10.02.5–10.02.10, characterizing in some detail the interiors of the asteroid 4 Vesta, the Moon, Mercury, Mars, Venus, and solid exoplanets. Finally, a summary of this chapter is included in Section 10.02.11.

10.02.2 Observational Methods

Important observational constraints on planetary interiors are provided by astronomical and geodetic methods, rotational and tidal variations, relationships between gravity and topography, magnetic field observations, planetary seismology, interpretations of geologic surface features and compositional variations, and laboratory studies of planetary materials and meteorites.

10.02.2.1 Geodesy

In the absence of seismic data, bulk composition and interior structure of a planet or satellite are mainly constrained by its mean density and mean MoI. The mean density of a planetary body is calculated from its mass and volume. To that end, it is necessary to infer the size and global shape of a planet or satellite from images acquired telescopically using micrometric or photographic techniques or by cameras on board spacecraft. The global shape or figure of a body depends on its mass, size, rotational and tidal state, and material strength. Detailed topographic maps of Mercury, Venus, the Moon, and Mars have been obtained by using Earth-based radar observations (Harmon, 2007; Harmon et al., 2001, 2011; Margot et al., 1999; Muhleman et al., 1995), radio occultation data, and radar and laser altimetry from orbiting spacecraft (Rappaport et al., 1999; Smith et al., 1999a; Zuber et al., 1992, 1994, 2008, 2012). Though the masses of planets and satellites have been known from astronomical observations for a long time, the most current and accurate values are based on measurements of spacecraft that landed, orbited, or flew by.

The gravitational field of a planet or satellite is closely related to the distribution of mass inside the body. Doppler tracking of a spacecraft using its radio communications signal determines its orbit or trajectory from which the gravitational field and the planetocentric constant GM (where G is the universal gravitational constant and M is total mass) can be inferred. The Doppler-tracking method is highly accurate in the case of orbiting spacecraft, so that the nominal error of the deduced value of the mean density of the body, for example, 3933.5 ± 0.4 kg m^{-3} in the case of Mars, is primarily due to uncertainties in the value of G (Esposito et al., 1992). The mean density is indicative of the bulk composition of the terrestrial planets and terrestrial-type bodies. The density of a given material is strongly dependent on porosity and local pressure and temperature conditions, the latter of which may rise to a few hundreds of GPa and thousands of kelvins deep inside large planets like Venus and Earth. Uncompressed densities vary from about 1000 kg m^{-3} for planetary ices, to 3000 kg m^{-3} for silicate rocks, up to 8000 kg m^{-3} for metallic iron. The densities of the Moon, the Jovian satellite Io, and the inner terrestrial planets range from about 3300 to 5500 kg m^{-3}, suggesting that the Moon is predominantly composed of rocky material, whereas Mercury mostly consists of metal (Figure 2). The Mercury-sized large icy satellites Ganymede, Callisto, and Titan have densities of only about 2000 kg m^{-3}. This implies that ice and rock/metal are present in about equal amounts in their interiors. Enceladus, Triton,

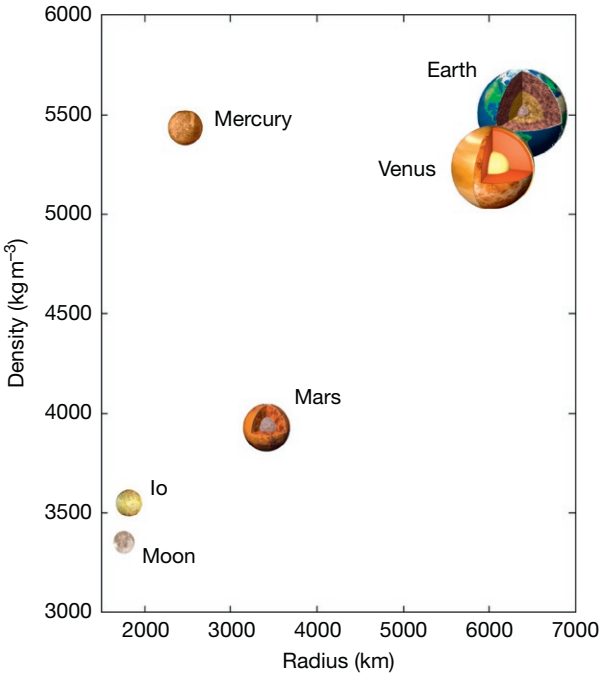

Figure 2 Radius–density relation of the terrestrial planets and the Moon. Note the unusually high mean density of Mercury implying that the planet's interior is predominantly composed of heavy elements such as iron.

Pluto, and Charon are icy bodies with similar ice–rock compositions (Hussmann et al., 2006).

The axial MoI of a planet or satellite C can be inferred from the precession of its rotation axis in the presence of external torques exerted on its equatorial bulge. Measurement of the precession rate might require the placement and long-term tracking of one or several landers on the surface of the body. For example, the combined analysis of Mars Global Surveyor (MGS) tracking and Mars Pathfinder and Viking lander range and Doppler data resulted in an improved value of the MoI factor of Mars, that is, the axial MoI normalized to the planet's mass times its radius squared, $C/MR_e^2 = 0.3644 \pm 0.0005$ (Konopliv et al., 2011), where R_e is Mars' equatorial radius fixed at 3396 km. This value is in good agreement with first determinations by Reasenberg (1977) and Kaula (1979) and much smaller than the MoI factor of 0.4 of a homogeneous sphere and is consistent with a significant concentration of mass toward the center due to a metallic core with a radius of about half that of the planet (Rivoldini et al., 2011; Schubert and Spohn, 1990; Sohl and Spohn, 1997; Sohl et al., 2005). The axial MoI of a planetary body can also be deduced from the figure of its gravitational field if the body is in hydrostatic equilibrium. However, this is a demanding requirement that is satisfied by only a few terrestrial-type bodies (see succeeding text).

10.02.2.2 Rotation and Tides

The internal mass distribution of a planetary interior can be inferred from its rotational and tidal response to external torques exerted on the planet or satellite if augmented by gravity field data (see **Chapter 10.04** in this volume). The torque applied to the body by the gravitational attraction of the Sun or a planet's satellite equals the inner product or tensor contraction of the body's inertia tensor and spin vector. Mercury and Venus have no satellites to affect their rotational states. The combined effect of the torques exerted by the tiny Martian moons, Phobos and Deimos, is much less than the torque exerted on Mars by the Sun (Van Hoolst et al., 2003). The torque applied to the Earth by the Moon decelerates the Earth's rotation due to tidal friction in the oceans and, to a minor extent, in the solid Earth (Platzman, 1984; Zharkov et al., 1996). In turn, the Moon is accelerated in its orbit and recedes from the Earth at a rate of a few centimeters per year. The rotation axes of Earth and Mars are tilted about axes normal to their orbital planes by 23.45°and 25.2°, respectively, thereby causing their spin axes to precess about the orbit normals under the influence of external gravitational torques.

Astronomical observations have revealed the precession rate of the Earth's spin axis and in turn the Earth's MoI. Radio tracking of the Viking and Mars Pathfinder landers, the stationary Opportunity Mars Exploration Rover, and MGS and Mars Odyssey orbiters has yielded similar information for Mars (Esposito et al., 1992; Folkner et al., 1997; Konopliv et al., 2006, 2011; Kuchynka et al., 2014; Yoder and Standish, 1997; Yoder et al., 2003). Laser ranging observations of the Moon, made possible by reflectors placed on the lunar surface during the Apollo program, have determined the Moon's rotational state (Dickey et al., 1994). Because of its orbital eccentricity and ellipsoidal shape, the Moon is subject to periodic changes in angular acceleration in response to gravitational torques exerted by the Sun and the Earth. The amplitude of the related 27-day forced libration in longitude has been used to infer the MoI of the Moon and the probable molten state of its central region (Khan et al., 2004; Williams et al., 2001; Yoder, 1981). In a similar way, measurements of Mercury's 88-day forced libration amplitude in longitude provide clues on the planet's internal mass distribution and coupling between core and mantle (Jehn et al., 2004; Margot et al., 2007, 2012; Peale, 1976, 1988). From a combined analysis of the rotational and low-degree gravitational field data, the radius of Mercury's outer liquid core and the presence of an inner solid core were inferred (Hauck et al., 2013; Rivoldini and Van Hoolst, 2013; Smith et al., 2012). It is unlikely, however, that the axial MoI of Venus could be derived from observations of its rotational state alone since the planet's retrograde rotation is extremely slow and its rotation axis is more or less perpendicularly aligned to the plane of its nearly circular orbit (Yoder, 1997).

10.02.2.3 Gravity and Topography

Gravimetric and magnetic methods utilize measurements of potential fields in the vicinity of planetary bodies. The long-wavelength part of the external gravitational field provides information on the structure of planetary interiors. Each element of mass in a planet or satellite contributes to the external gravitational field according to the Newton's law of gravitation. The gravitational force at a point exterior to the planet can be derived from the gradient or directional derivative of the gravitational potential caused by the total contribution of all mass elements when integrated over the entire volume of the body. In recognition of the first gravity experiments conducted by Galileo Galilei who measured fall times of objects possibly dropped from the leaning tower of Pisa, gravitational acceleration is given in units of $1\ \text{mGal} = 10^{-5}\ \text{m s}^{-2}$.

The gravitational fields of planetary bodies are measured from orbiting spacecraft. The technique uses the Doppler effect on radio signals transmitted from the Earth to the spacecraft and back. The frequency shift of the radio signals returned by the spacecraft relative to the signal emitted from the ground station is proportional to the velocity component along the direction of vision or line of sight and allows the calculation of the line-of-sight acceleration of the spacecraft (Dehant et al., 2009, 2011; Janle and Meissner, 1986). These data can be used to calculate the gravitational field at a resolution determined by the altitude and the frequency of signal transmission to the spacecraft. Laser altimetry from orbiting spacecraft has been used to determine the topography of the northern hemisphere of Mercury, the Moon, and Mars with high accuracy. Radar altimetry data obtained by the Magellan spacecraft have provided topographic maps of Venus. The correlation of topography with the distribution of the Bouguer gravity (gravity corrected for contributions of topographic masses above a well-defined reference level) can be used to infer the degree of isostatic compensation of topography and the depth at which stresses are fully compensated due to rheological and/or compositional changes. Gravity anomalies provide important constraints on elastic lithosphere thickness, crust thickness, crust density, and load density and can be interpreted in

terms of chemically or thermally induced lateral and depth variations of density. However, these interpretations suffer from the nonuniqueness inherent in any inversion of the gravity field (see **Chapter 10.05** in this volume).

The external gravitational field of a planet or satellite is generally described by a spherical harmonic expansion of the gravitational potential as a function of latitude, longitude, and radial distance to the center of mass. The frequency content of the amplitude spectrum of the gravitational potential gives insight into the rheology and the mechanical and thermal properties of the lithosphere, the outer rigid shell of a planet or satellite. The leading term in the spherical harmonic expansion of the external gravitational potential is the ratio between the planetocentric constant GM and the radial distance r representing the gravitational potential of the mass of the body concentrated in a point at its center of mass. The next terms of the spherical harmonic expansion are inversely proportional to r^3 and involve higher moments of the gravitational field caused by ellipsoidal distortions of the internal mass distribution. The magnitudes of these distortions are related to coefficients $J_2 = -C_{2,0}$ and $C_{2,2}$ for polar oblateness and equatorial ellipticity of the gravitational field, respectively. When the body is in hydrostatic equilibrium, its mean MoI can be deduced from the knowledge of these coefficients with important implications for the internal structure. However, if the lithosphere is thick and strong enough to support stresses associated with surface or subsurface mass anomalies, the planet or satellite may substantially deviate from hydrostatic equilibrium. Furthermore, mantle density anomalies and core–mantle boundary undulations may contribute to deviations from hydrostatic equilibrium. Accordingly, the Moon and Mercury are not expected to be fully hydrostatically compensated. The Earth is reasonably close to this state, but Mars is not, due to the uncompensated portion of the Tharsis uplift (Kaula, 1979; Reasenberg, 1977). Though the gravitational field of Venus is known quite well, it is not known if the planet is in hydrostatic equilibrium. Therefore, the gravitational field cannot be used to give a reliable value of the planet's MoI. A number of solid bodies in the outer solar system including the large icy satellites of Jupiter and Saturn, Ganymede, Callisto, and Titan, and the strongly tidally heated Jovian satellite Io are likely to be in hydrostatic equilibrium (see **Chapter 10.18** in this volume). The quadrupole gravitational fields of these Jovian satellites have been used to infer their moments of inertia (Schubert et al., 2004).

10.02.2.4 Magnetic Fields

Magnetic field observations provide constraints on the interior structure of planets and moons (see **Chapter 10.06** in this volume). The existence of an intrinsic planetary magnetic field on a global scale is a conclusive evidence that the body has a mobile, highly electrically conducting fluid region in its interior within which dynamo action creates the magnetic field. In the case of terrestrial planets, the site of magnetic field generation is a metallic core that is at least partially liquid. Earth and Mercury are the only terrestrial planets with a magnetic field that is unambiguously generated in its core. Mercury has a large iron core (Schubert et al., 1988) that is at least partially liquid (Margot et al., 2007) and a global magnetic field that must be generated therein (Anderson et al., 2011, 2012). Jupiter's icy satellite Ganymede is the only other terrestrial-like solar system body whose magnetic field is generated by an active liquid metallic core dynamo. The discovery of Ganymede's magnetic field provided crucial evidence that the satellite is differentiated and has a metallic core (Schubert et al., 1996). The absence of a planetary magnetic field, as in the cases of Venus and Mars, only implies the nonexistence of an active dynamo; it does not imply the nonexistence of a metallic core nor does it require a metallic core to be solid.

An external planetary magnetic field can be represented by a spherical harmonic expansion of its magnetic potential in a manner similar to the representation of the gravitational field. It is possible to identify the core dynamo field in the spectrum of the magnetic field spherical harmonic coefficients and thereby determine the radius of the core. This procedure has been used by Voorhies et al. (2002) to estimate the radius of the Earth's core as 3512 ± 64 km, in good agreement with the seismological radius (see also Elphic and Russell, 1978).

Though not in possession of global internally generated magnetic fields at present, the Moon (Halekas et al., 2001; Hood et al., 2001; Lin et al., 1998; Russell et al., 1973, 1975) and Mars (Acuña et al., 1998, 1999; Connerney et al., 2004) have localized magnetic fields associated with crustal remanent magnetization. On the assumption that the crustal magnetization was acquired when these bodies had active dynamos in the past, even the crustal magnetization is evidence for the existence of a metallic core in these bodies. This is particularly important for the Moon that has a small metallic core that is difficult to detect by any method (Garcia et al., 2011; Weber et al., 2011). Alternatively, Hood and Huang (1991) had proposed large-scale magnetization in lunar basin-forming impacts caused by plasma-induced antipodal amplification of ambient magnetic fields to explain the correlation of the largest magnetic field strengths with the antipodes of the largest lunar impact basins. The spatial variation of crustal magnetization and its associated magnetic fields also provide information on the internal structure of a body at shallow depth and the internal and surface processes that have affected the crust.

10.02.2.5 Electromagnetics

The phenomenon of electromagnetic induction can be utilized to probe planetary interiors. The method takes advantage of the electrically conducting nature of planetary materials and the time variability of the magnetic fields experienced by planetary bodies. If an electrically conducting object experiences a time-variable magnetic field, electrical currents are induced in the object (Faraday's law of induction). These induced currents in turn generate a magnetic field.

If the inducing and induced magnetic fields can be measured, then the electrical conductivity of the object can be inferred. This method has been successfully used to infer the electrical conductivity of the Earth (Banks, 1969; Chapman and Price, 1930; Hobbs, 1987; Kuvshinov and Olsen, 2006; Lahiri and Price, 1939; Rikitake, 1966; Roberts, 1986; Schuster, 1889; Tarits, 1994) and the Moon (Schubert and Schwartz, 1969; Sonett, 1982; Sonett et al., 1971). It has also been used to find subsurface liquid salt water oceans on the Galilean satellites Europa, Ganymede, and Callisto (Khurana et al.,

1998; Kivelson et al., 1999, 2000, 2002, 2004; Zimmer et al., 2000) and a subsurface magma ocean on Io (Khurana et al., 2011). In the case of the Earth, time variations in the external magnetic field are forced by variable ionospheric and magnetospheric current systems. The Moon experiences the variable magnetic field of the solar wind when it is outside the Earth's magnetosphere. The Galilean satellites experience the variability of the rotating, tilted Jovian magnetic field. On Earth, the external forcing magnetic field can be separated from the internal induced magnetic field by a network of surface magnetometers. More recently, satellite data have also been used for this purpose (Constable and Constable, 2004; Olsen, 1999). For the Moon, magnetometers on the surface and an orbiting spacecraft measured the solar wind forcing field and inductive response during the era of lunar exploration by Apollo spacecraft in the late 1960s and early 1970s. A magnetometer on the Galileo spacecraft measured the induced magnetic fields of Io, Europa, Ganymede, and Callisto. Knowledge of electrical conductivity inside a planetary body indirectly constrains the composition, temperature, and volatile content of the body through the dependence of the conductivity on these properties (Hood, 1986; Hood and Jones, 1987; Hood and Sonett, 1982; Hood and Zuber, 2000; Hood et al., 1982; Sonett et al., 1972). The electromagnetic sounding approach involves two inversion steps, inference of the electrical conductivity from magnetic measurements and inference of composition, temperature, and volatile content from the conductivity.

Magnetic field measurements obtained during the passage of the Moon through the Earth's geomagnetic tail provide a means of detecting the lunar core (Hood et al., 1999). For several days each month, the Moon passes through the north and south lobes of the geomagnetic tail and experiences a vacuum-like environment with a near steady uniform magnetic field. This results in an induced lunar magnetic dipole that acts to exclude the tail lobe field from the Moon's interior. The induced magnetic dipole is produced by electric currents that flow near the surface of the highly electrically conducting metallic core (Hood et al., 1999). The lunar-induced magnetic dipole has been detected by the magnetometer on the Lunar Prospector (LP) spacecraft; the measured value of the induced dipole moment implies a core of radius 340 ± 90 km (Hood et al., 1999) in good agreement with recent estimates based on reanalysis of Apollo seismic data (Garcia et al., 2011; Weber et al., 2011).

10.02.2.6 Seismology

The propagation of seismic waves following quakes or impacts can be used to infer the structure of planetary interiors. Lognonné (2005) and Lognonné and Mosser (1993) had provided reviews on planetary seismology (see **Chapter 10.03** in this volume). Whereas surface waves are confined to near-surface layers, body waves travel through the interior. The first body waves arriving at a seismic station are longitudinal or P-waves that involve material compression and rarefaction. The second body waves are transverse or S-waves involving shear motion perpendicular to the direction of propagation. Body waves are subject to reflection, transmission, and conversion from P- to S-waves and vice versa at internal boundaries at which prominent density and seismic velocity changes occur. A network of at least four seismic stations is required to infer the source location from a comparison of the seismic station records. Free oscillations on a global scale can be excited if the magnitudes of seismic events are sufficiently large.

For the Earth, seismology has not only revealed the existence of a metallic core surrounded by a rocky mantle but also shown that the core consists of a solid inner core composed of iron and nickel and a liquid outer shell containing a mixture of light elements. The analysis of surface waves has provided important clues on the chemical layering of the Earth's crust. Though seismic stations were placed on the Moon's surface during the Apollo exploration era, the collected data were unable at that time to confirm the presence or absence of a small metallic core and did not allow construction of detailed models of the lunar crust and mantle. As discussed later, a reanalysis of the Apollo seismic data has revealed more about the lunar interior. Seismic instruments placed on the surface of Mars by the Viking mission did not provide data that could be used to determine the planet's internal structure. A promising target for seismic exploration in the outer solar system is the Jovian satellite Europa owing to the presence of a satellite-wide internal liquid layer beneath its outer ice shell. A passive seismic experiment placed on the surface of Europa would be able to detect seismic activity generated by the formation of cracks, tidally induced quakes, or natural impacts. The thickness of the ice shell could be obtained from low-frequency band observations (0.1–10 Hz) of trapped surface waves (Kovach and Chyba, 2001; Lee et al., 2003; Panning et al., 2006).

10.02.2.7 Surface Geology and Composition

The geology and composition of a planet's surface provide important clues into what lies inside the body. These glimpses into the interior, though generally qualitative in nature, are valuable nonetheless and complement more quantitative constraints on internal structure.

The basaltic crust of Mercury and the basaltic lowlands of Venus are evidence of the internal differentiation of these bodies. The anorthositic lunar highlands not only attest to the differentiation of the Moon but also argue for a global-scale magma ocean early in lunar history (Smith et al., 1970; Warren, 1985; Wood et al., 1970). Mercury's high density suggests it is iron-rich, yet spectral evidence suggests that its surface is poor in oxidized iron (Blewett et al., 1997; Vilas, 1985), consistent with the segregation of its iron into a central core following differentiation under reducing conditions (Schubert et al., 1988; Sprague et al., 1994).

The crust dichotomy of Mars represents an ancient feature of early Noachian age (>3.5–3.7 Gy) that is preserved in the surface geology and tectonics, the cratering record, and the planet's gravity and magnetic field. The heavily cratered southern highland crust on Mars and the resurfaced northern lowlands of the planet indicate early differentiation and internal dynamic activity (Watters and McGovern, 2005), though removal of the northern crust by one or multiple giant impacts about 4 Gy has also been hypothesized (Wilhelms and Squyres, 1984). However, the detection of quasicircular depressions in the northern lowlands, interpreted as buried impact craters and basins, suggests a similar age for the lowland and the ancient

southern highland crust (Frey et al., 2002). This favors an endogenic origin of the crustal dichotomy involving dynamic processes like degree-1 mantle convection (Lingenfelter and Schubert, 1973; Roberts and Zhong, 2006; Schubert and Lingenfelter, 1973; Zhong and Zuber, 2001), thin-crust formation by early plate tectonics, and the solidification and convective instability of a pristine magma ocean on Mars (Elkins-Tanton et al., 2003b). The ancient dichotomy boundary was modified then by fluvial, aeolian, and glacial processes, as well as by widespread volcanic and sedimentary resurfacing of the northern lowlands (Watters and McGovern, 2005).

Surface geology and signs of endogenic activity are particularly important for inferring the internal structure of outer solar system moons. The heavily cratered surfaces of Jupiter's icy moon Callisto and Saturn's icy moon Rhea support the inference that these bodies are essentially undifferentiated (ice from rock) (Anderson and Schubert, 2007; Schubert et al., 2004). In contrast, the highly modified surfaces of the Jovian satellites Ganymede and Europa and the Saturnian satellite Enceladus are consistent with the separation of ice and rock in their interiors (Porco et al., 2006; Schubert et al., 2004, 2007). The ubiquitous and ongoing volcanic activity of Jupiter's satellite Io leaves little doubt that the moon has differentiated into an iron-rich core and silicate mantle (Moore et al., 2006). Thermal anomalies detected in Enceladus' south polar region and the active plumes spewing water from beneath the south polar surface of Enceladus (Porco et al., 2006; Spencer et al., 2006) provide additional persuasive evidence for the formation of a rock core and ice mantle inside this body.

While not definitive in themselves, surface geologic and compositional data help to constrain models of planetary and satellite interiors, especially when more quantitative observations are limited.

10.02.2.8 Material Properties

There are only a few kimberlite rock samples brought to the Earth's surface by violent volcanic eruptions that directly probe the deep interior of a terrestrial planet. Diamond deposits occasionally found in kimberlite rocks suggest that confining pressure must have exceeded the pressure at which diamonds are stable. Meteorites originally released from the surfaces of the Moon and Mars during one or several large impact events represent another important data source on the composition of terrestrial planet interiors. Much of our knowledge about the interior structure and evolution of the Earth and other terrestrial planets, however, comes from high-pressure mineral physics that includes laboratory experiments and computational studies. Bass (2004) summarized current and future research activities in this highly interdisciplinary and rapidly evolving field of research (see **Chapter 2.01**).

Earth and planetary material properties are affected by variable compositions and thermodynamic conditions. The core sulfur content may range from close, to eutectic, to iron-rich compositions with important implications for the physical state and density stratification of planetary cores (Balog et al., 2003; Fei et al., 1995, 1997; Kavner et al., 2001; Sanloup et al., 2000) due to the substantial melting point reduction with increasing sulfur concentration (Boehler, 1992, 1996a; Buono and Walker, 2011; Chudinovskikh and Boehler, 2007). Mantle rheology is affected by predominant mineral phase assemblages, water content, and typical mineral grain size distribution. It is possible that mantle mineralogies of other terrestrial bodies are not dominated by olivine but rather by mixtures of pyroxene minerals. Experimental and theoretical studies of two-phase rheologies (e.g., rock–volatile and rock–melt) are particularly useful for a better understanding of the influence of volatiles like water and carbon and solid gas hydrates on deeply situated geodynamic processes (Sloan, 2003), like the subduction of lithospheric plates on Earth, the rheological behavior of crust and mantle rocks, the kinetics of pressure-induced mineral phase transformations, and the extraction of partial mantle melts (Bass, 2004).

Nowadays, sophisticated tools are available to study the properties of matter under extreme pressure and temperature conditions that prevail in planetary interiors (Liebermann, 2005). From shock and static compression experiments using diamond-anvil facilities, densities, equation-of-state parameters (Hemley, 2006; Hemley and Ashcroft, 1998), and elastic properties of solid mineral phase assemblages (Anderson et al., 1992; Bina and Helffrich, 1992), as well as high-pressure properties of melts (Boehler, 1996b,c; Nishida et al., 2008), are derived. In these experiments, relatively small samples are subjected to conditions that may prevail deep in the Earth's mantle or even in its metallic core ($P > 135$ GPa, $T > 3000$ K). Future experiments are expected to provide important information on high-pressure transport properties like thermal conductivity and kinematic viscosity, the kinetics of chemical reactions at the core–mantle boundary, and mineral phase equilibriums up to several tens of GPa. While inelastic x-ray diffraction methods are used to measure sound velocities at very high pressures and temperatures, neutron scattering observations are well suited to determine the structural properties of silicate melts and aqueous solutions (Bass, 2004). Laboratory experiments need to be augmented by high-performance computations, for example, to simulate diffusion-limited transport processes occurring at atomic scales. These simulations are important to address the influence of oxygen fugacity on mantle rock phase transformation kinetics and the element solubility of light-element admixtures in liquid iron alloys (Badding et al., 1991; Wood, 1993).

10.02.3 Interior Structure and Composition

In the following, we consider two- and three-layer structural models before we discuss radially symmetrical, depth-dependent interior structure models.

10.02.3.1 Two- and Three-layer Structural Models

Models of the internal density distribution of terrestrial planets suffer from an inherent nonuniqueness since there are usually fewer constraints than unknowns. These models are required to satisfy two constraints, the mean density ρ as derived from the total radius R and mass M and the mean MoI I that can be determined from the quadrupole moments of the gravitational field and the precession rate of the spin axis.

The mean density of a two-layer spherical body is given by

$$\rho R^3 = (\rho_c - \rho_m)R_c^3 + \rho_m R^3 \quad [1]$$

from which the relative core radius R_c/R, core mass fraction M_c/M, and dimensionless mean MoI factor are obtained according to

$$\frac{R_c}{R} = \left(\frac{\rho - \rho_m}{\rho_c - \rho_m}\right)^{1/3} \quad [2]$$

$$\frac{M_c}{M} = \frac{\rho_c}{\rho}\left(\frac{R_c}{R}\right)^3 = \frac{\rho_c}{\rho}\frac{(\rho - \rho_m)}{(\rho_c - \rho_m)} \quad [3]$$

and

$$\text{MoI} = \frac{I}{MR^2} = \frac{2}{5}\left(\frac{(\rho - \rho_m)^{5/3}}{\rho(\rho_c - \rho_m)^{2/3}} + \frac{\rho_m}{\rho}\right) \quad [4]$$

respectively. For stably stratified layering, the corresponding increase of density with depth is equivalent to the requirement $\rho_c > \rho$ and $0 < \rho_m < \rho$. In Figure 3, contours of MoI are shown for plausible ranges of core and mantle densities normalized to the mean density, ρ_c/ρ and ρ_m/ρ, respectively.

For a rapidly rotating planetary body in hydrostatic equilibrium, the mean MoI as a measure for mass concentration toward the center can be obtained from the dimensionless polar MoI factor, C/MR^2, and the second-degree coefficient of the spherical harmonic expansion of the gravity field, J_2, by

$$\frac{I}{MR^2} = \frac{C}{MR^2} - \frac{2}{3}J_2 \quad [5]$$

where

$$J_2 = \frac{1}{MR^2}\left[C - \frac{A+B}{2}\right] = -C_{2,0} \quad [6]$$

is the gravitational oblateness and A, B, and C are the planet's principal equatorial and polar moments of inertia, where $A < B < C$, respectively (Kaula, 1979; Reasenberg, 1977). A more comprehensive account including minor nonhydrostatic corrections to the mean MoI factor due to symmetrical distributions of topographical masses, like the Tharsis rise on Mars, is provided by Sohl et al. (2005).

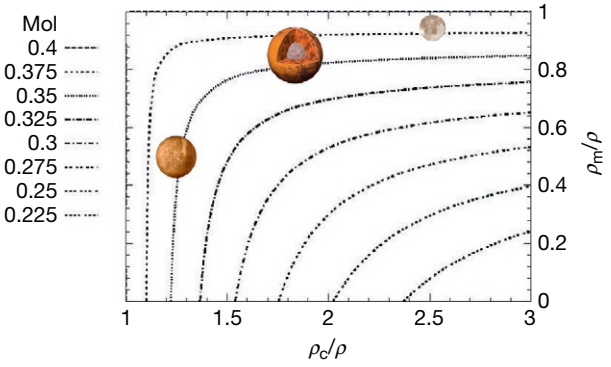

Figure 3 Contours of the mean moment of inertia factor MoI for two-layer structural models of planetary interiors as a function of core and mantle density ρ_c and ρ_m, respectively, relative to mean density ρ. The symbols shown in the diagram represent putative locations of the Moon, Mars, and Mercury.

The gravitational acceleration g_r and hydrostatic pressure p_r as a function of radial distance from the center of the planet r are given by

$$g_r = \frac{4}{3}\pi G r \rho_c \quad 0 \le r \le R_c$$

$$= \frac{4}{3}\pi G r\left[\rho_m + (\rho_c - \rho_m)\left(\frac{R_c}{r}\right)^3\right] \quad R_c \le r \le R \quad [7]$$

and

$$p_r = \frac{4}{3}\pi G \rho_m R_c^3(\rho_c - \rho_m)\left[\frac{1}{r} - \frac{1}{R}\right] + \frac{2}{3}\pi G \rho_m^2(R^2 - r^2) \quad R_c \le r \le R$$

$$= \frac{2}{3}\pi G \rho_c^2(R_c^2 - r^2) + \frac{2}{3}\pi G \rho_m^2(R^2 - R_c^2) + \frac{4}{3}\pi G \rho_m R_c^3(\rho_c - \rho_m)\left[\frac{1}{R_c} - \frac{1}{R}\right] \quad 0 \le r \le R_c \quad [8]$$

respectively, where G is the gravitational constant (Turcotte and Schubert, 2002).

Given the paucity of information available, three-layer models representing the core, the mantle, and the crust can be considered as a useful approximation to the structure of terrestrial planet interiors. The corresponding structural equations are given by

$$\rho = \rho_s + (\rho_c - \rho_m)\left(\frac{R_c}{R}\right)^3 + (\rho_m - \rho_s)\left(\frac{R_m}{R}\right)^3 \quad [9]$$

$$\text{MoI} = \frac{I}{MR^2} = \frac{2}{5}\left(\frac{\rho_s}{\rho} + \frac{\rho_c - \rho_m}{\rho}\left(\frac{R_c}{R}\right)^5 + \frac{\rho_m - \rho_s}{\rho}\left(\frac{R_m}{R}\right)^5\right) \quad [10]$$

where the core radius R_c, the crust–mantle radius R_m, the crust density ρ_s, the mantle density ρ_m, and the core density ρ_c are unknown. Even two-layer interior structure models lacking a crust layer ($\rho_s = 0$, $R_m = R$) would have fewer constraints than unknowns, that is, ρ_c, R_c, and ρ_m. We refer the reader to Sohl et al. (2009) for a compilation of two- and three-layer structural model determinations of the terrestrial planets, the Moon, and selected Jovian and Saturnian satellites in the tabular form.

10.02.3.2 Depth-Dependent Structural Models

The equation for the determination of the density distribution in the regions of the Earth with adiabatic temperature profiles was obtained by Williamson and Adams (1923). The first current models of the Earth were constructed at the beginning of the 1940s by Bullen (1947), who introduced the subdivision of the Earth's interiors into characteristic zones that is still valid today. Deviations from adiabaticity, the presence of phase transition zones, and changes of the chemical composition result in additional terms to the Williamson–Adams equation. These effects are described in detail for the Earth's interior in the first chapter of Zharkov et al. (1996).

A commonly used approach to modeling the interior structure of a terrestrial planet given its mass, radius, and MoI (see Wood et al. (1981) for a review) converts the estimated bulk composition into a mineralogical model and adopts potential temperatures for

the mantle layers and the core from thermal history calculations. The potential temperature is the mantle temperature extrapolated adiabatically to the surface pressure. The radial density distribution is then calculated under the assumption of hydrostatic and thermal equilibrium using an equation of state to correct for compression and thermal expansion. The total mass and the MoI are calculated from the model and compared with the data. This approach can be modified by simultaneously calculating the thermal and mechanical structure of a terrestrial body (e.g., Sohl and Spohn, 1997; Wagner et al., 2011, 2012). Standard-temperature-and-pressure values of the density, the bulk modulus, and the thermal expansivity are calculated from laboratory data for the individual layers of the model.

10.02.3.2.1 Governing equations

If a spherically symmetrical planet in perfect mechanical equilibrium and thermal steady state is assumed, the following set of differential equations for mass m, iron mass m_{Fe}, mean MoI I, acceleration of gravity g, pressure p, and heat flux q can be derived from fundamental principles (Wagner, 2014):

$$\frac{\mathrm{d}m}{\mathrm{d}r} = 4\pi r^2 \rho_{\mathrm{r}} \quad [11]$$

$$\frac{\mathrm{d}m_{\mathrm{Fe}}}{\mathrm{d}r} = x_{\mathrm{Fe}} \frac{\mathrm{d}m}{\mathrm{d}r} \quad [12]$$

$$\frac{\mathrm{d}I}{\mathrm{d}r} = \frac{8}{3}\pi r^4 \rho_{\mathrm{r}} \quad [13]$$

$$\frac{\mathrm{d}g}{\mathrm{d}r} = 4\pi G \rho_{\mathrm{r}} - 2\frac{g}{r} \quad [14]$$

$$\frac{\mathrm{d}p}{\mathrm{d}r} = -\rho_{\mathrm{r}} g \quad [15]$$

$$\frac{\mathrm{d}q}{\mathrm{d}r} = \rho_{\mathrm{r}} \varepsilon_{\mathrm{r}} - 2\frac{q}{r} \quad [16]$$

where r is the radial distance from the center of the planet, G is the gravitational constant, ρ is the density, x_{Fe} is the concentration of iron per unit mass, and ε is the specific heat production rate. The subscript r indicates quantities that are local functions of p, T, and composition.

Heat is primarily carried by conduction across the stagnant outer portion of a planet's silicate shell and the top and bottom thermal boundary layers of mantle convection. The corresponding radial temperature gradient is given by

$$\frac{\mathrm{d}T}{\mathrm{d}r} = -\frac{q}{k_{\mathrm{r}}} \quad [17]$$

where k is the thermal conductivity. Within the convective portion of the silicate shell and the outer liquid core shell, the temperature gradient can be approximated by the adiabatic temperature gradient (Stacey, 1977)

$$\frac{\mathrm{d}T}{\mathrm{d}r} = T\frac{\gamma_{\mathrm{r}}}{K_{S,\mathrm{r}}}\frac{\mathrm{d}p}{\mathrm{d}r} = T\frac{\gamma_{\mathrm{r}}\rho_{\mathrm{r}}}{\Phi_{\mathrm{r}}}\frac{\mathrm{d}p}{\mathrm{d}r} = \left(\frac{\mathrm{d}T}{\mathrm{d}r}\right)_{\mathrm{ad}} \quad [18]$$

where $\gamma = \alpha K_S/\rho c_P$ is the thermodynamic Grüneisen parameter, α is the thermal expansivity, c_P is the specific heat, and K_S is the adiabatic bulk modulus defined as

$$\frac{1}{K_S} = \frac{1}{\rho}\left(\frac{\partial \rho}{\partial p}\right)_S \quad [19]$$

Finally, p, K_S, and the shear modulus G_μ are related to the seismic velocities

$$V_{P,\mathrm{r}} = \sqrt{\frac{K_{S,\mathrm{r}} + \frac{4}{3}G_{\mu,\mathrm{r}}}{\rho_r}} \quad [20]$$

and

$$V_{S,\mathrm{r}} = \sqrt{\frac{G_{\mu,\mathrm{r}}}{\rho_r}} \quad [21]$$

of longitudinal P- and transversal S-waves, respectively, from which the seismic parameter

$$\Phi_{\mathrm{r}} = \frac{K_{S,\mathrm{r}}}{\rho_{\mathrm{r}}} = V_{P,\mathrm{r}}^2 - \frac{4}{3}V_{S,\mathrm{r}}^2 \quad [22]$$

can be derived.

The radial positions of pressure-induced mantle phase boundaries like the exothermic olivine–β-spinel (wadsleyite) and β-spinel (wadsleyite)–γ-spinel (ringwoodite) transitions and the endothermic γ-spinel (ringwoodite)–perovskite transition can be obtained from the intersections of the temperature profile calculated from eqns [16] to [18] and the specific Clausius–Clapeyron curves.

The set of basic differential eqns [11]–[18] can be separated into two subsets that are coupled through the density ρ. The mechanical properties of the interior are calculated from eqns [11] to [15], while eqns [16]–[18] give the thermal structure of the model. These equations have to be supplemented with an appropriate equation of state to include pressure-induced compression and thermal expansion effects on the density and are discussed in more detail in the succeeding text (Stacey et al., 1981) and illustrated in **Figure 4**.

10.02.3.2.2 Boundary conditions

The set of basic differential eqns [11]–[18] can be solved by numerical integration with respect to the following boundary conditions. The central boundary conditions at $r = 0$ are

$$m = 0;\ m_{\mathrm{Fe}} = 0;\ \theta = 0;\ g = 0;\ p = p_{\mathrm{c}};\ q = 0;\ T = T_{\mathrm{c}} \quad [23]$$

The surface boundary conditions at $r = R$ are

$$m = M;\ m_{\mathrm{Fe}} = M_{\mathrm{Fe}};\ \theta = I;\ g = g_{\mathrm{p}};\ p = p_{\mathrm{p}};\ q = q_{\mathrm{p}};\ T = T_{\mathrm{p}} \quad [24]$$

While the mass M and the mean surface values of gravity g_{p}, pressure p_{p}, and temperature T_{p} are derived from spacecraft and Earth-based observations, the surface heat flux q_{p} of most terrestrial bodies other than the Earth is unknown at present. Since there are three observational constraints on the model, the mass M, the radius R, and the mean MoI I, respectively, three parameters are adjustable, the values of which are iteratively adjusted such that the observational constraints can be satisfied. These parameters are the central pressure p_c, the central temperature T_c, and the pressure at the core–mantle boundary p_{cmb}. For the sake of rapid convergence to the successful solution, the initial set of starting parameters is constrained to lie sufficiently close to the final set of parameters. An educated guess of the initial set can be obtained by using the previously mentioned analytic solutions for a three-layer structural model, having the planet's mass, iron mass fraction,

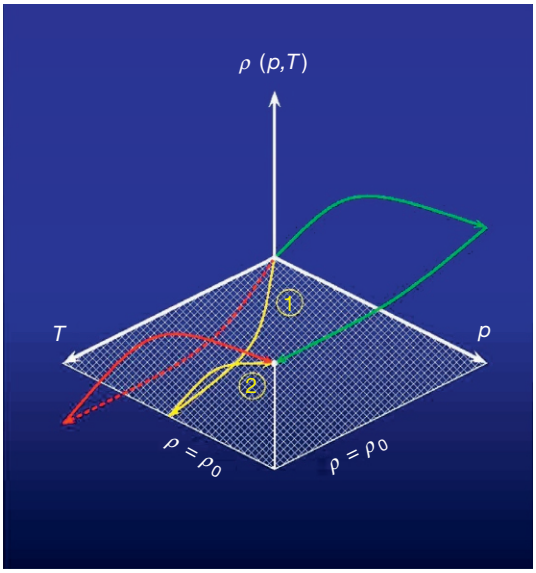

Figure 4 Schematic view of the extrapolation of density $\rho(p, T)$ to elevated pressures p and temperatures T. The origin of the coordinate system refers to an arbitrarily chosen reference density $\rho_0(p_0, T_0)$ at fixed (standard) pressure and temperature conditions p_0 and T_0, respectively. First, the increase of thermal pressure caused by thermal expansion is calculated (path 1); then, the isothermal Birch–Murnaghan equation (path 2) is applied to account for pressure-induced compression. Also shown are alternate thermodynamic paths. Modified from Wood JA, Anderson DL, Buck WR, et al. (1981) Geophysical and cosmochemical constraints on properties of mantles of the terrestrial planets. In: Project BVS (ed.) *Basaltic Volcanism on the Terrestrial Planets*, pp. 633–699. New York: Pergamon.

basaltic crust density, and homogeneously distributed crust/mantle heat sources (Turcotte and Schubert, 2002).

10.02.3.2.3 Equation of state

A convenient method to calculate density as a function of depth, first applied to seismological data from the Earth's deep interior, relies on the assumption of hydrostatic pressure (eqn [15]) and adiabatic temperature (eqn [18]) conditions and is sometimes referred to as the *Williamson–Adams* method honoring its authors. The resultant adiabatic density gradient

$$\frac{\mathrm{d}\rho}{\mathrm{d}r} = -\frac{\rho_\mathrm{r} g_\mathrm{r}}{\Phi_\mathrm{r}} = \Phi_\mathrm{r}^{-1}\frac{\mathrm{d}p}{\mathrm{d}r} \qquad [25]$$

can be readily obtained from insertion of eqns [19] and [22] in [15] and rearranging terms. Later, a correction term was added to address temperature deviations from an adiabatic reference state. These are caused by thermal boundary layers of mantle convection and/or compositional changes and pressure-induced mineral phase transformations in a silicate mantle, giving rise to superadiabatic temperature gradients

$$\tau = \frac{\mathrm{d}T}{\mathrm{d}r} - \left(\frac{\mathrm{d}T}{\mathrm{d}r}\right)_\mathrm{ad} \qquad [26]$$

that may profoundly affect the density stratification. The overall density gradient is then given by

$$\frac{\mathrm{d}\rho}{\mathrm{d}r} = \Phi_\mathrm{r}^{-1}\frac{\mathrm{d}p}{\mathrm{d}r} + \alpha_\mathrm{r}\rho_\mathrm{r}\tau_\mathrm{r} \qquad [27]$$

and can be derived from the ambient density ρ_r and the seismic parameter Φ_r if adiabatic compression dominates (first term). In the event of perfect adiabaticity, τ_r will equal zero, and the superadiabatic correction (second term) would vanish.

To interpret density profiles inferred from seismological observations in terms of compositional changes and temperature anomalies, it is necessary to consider decompressed values of density. Reliable extrapolation to zero-pressure and room-temperature conditions requires laboratory measurements of thermodynamic material properties be experimentally determined at high pressures and temperatures. Extrapolation between different thermodynamic states represents a principal source of uncertainty in density modeling because of incomplete knowledge of the material parameters involved. For technical reasons, laboratory measurements are usually carried through under isothermal conditions.

The isothermal bulk modulus is then defined as

$$\frac{1}{K_T} = \frac{1}{\rho}\left(\frac{\partial\rho}{\partial p}\right)_T \qquad [28]$$

and can be related to K_S by using the isothermal–adiabatic transformation

$$\frac{K_S}{K_T} = 1 + \gamma\alpha T \qquad [29]$$

if the Grüneisen parameter γ and thermal expansivity α are specified. A linearly pressure-dependent expression for K_T is frequently used, that is,

$$K_T = K_{0T} + \frac{\mathrm{d}K_{0T}}{\mathrm{d}p}p = K_{0T} + K_0' p \qquad [30]$$

and taken as $\gamma = \gamma_0(\rho/\rho_0)^{-l}$, with index 0 referring to an arbitrarily chosen reference state at fixed (standard) pressure and temperature conditions p_0 and T_0, respectively, l = const., and constant first pressure derivative K_0'. Insertion of eqn [30] in [28] and subsequent integration yield

$$p = \frac{K_{0T}}{K_0'}\left[\left(\frac{\rho}{\rho_0}\right)^{K_0'} - 1\right] \qquad [31]$$

which is occasionally referred to as *Murnaghan's* equation. The corresponding density relative to its reference value is then given by

$$\frac{\rho}{\rho_0} = \left(1 + \frac{K_0'}{K_{0T}}p\right)^{1/K_0'} \qquad [32]$$

The density distribution within a chemically homogeneous layer was extended by Birch (1952) who suggested use of a higher-order isothermal finite-strain equation of state to correct for pressure-induced compression and to apply temperature corrections through calculation of the thermal pressure contribution (Stacey et al., 1981).

For example, an isothermal *Birch–Murnaghan* equation truncated at third-order in strain involves K_{0T} and K_0' to correct for pressure-induced compression and the product $\alpha_0 \times K_{0T}$ to correct for thermal pressure effects, according to (Anderson and Baumgardner, 1980)

$$p = \frac{3K_{0T}}{2}\left[\left(\frac{\rho}{\rho_0}\right)^{7/3} - \left(\frac{\rho}{\rho_0}\right)^{5/3}\right] \left\{1 + \frac{3}{4}\left(K_0' - 4\right)\left[\left(\frac{\rho}{\rho_0}\right)^{2/3} - 1\right]\right\} + p_{\text{th}} \quad [33]$$

Since internal temperatures of the terrestrial planets usually exceed the Debye temperature, the quasiharmonic approximation is valid (Anderson et al., 1992) and the thermal pressure given by

$$p_{\text{th}} = \int_{T_0}^{T}\left(\frac{\partial p}{\partial T}\right)_V \mathrm{d}T = \int_{T_0}^{T} \alpha K_T \mathrm{d}T \approx \alpha_0 K_{0T}(T - T_0) \quad [34]$$

can be used in eqn [33] to include the temperature effect in the equation-of-state parameters (Anderson, 1984). We refer the reader to Sohl et al. (2009) for a compilation of equation-of-state parameters of selected Mg- and Fe-rich mantle mineralogical phase assemblages and core constituents and references therein.

In summary, the simplicity of the *Williamson–Adams* method is partly counterbalanced by the disadvantage that seismological data are not frequently available for terrestrial planets other than the Earth and the Moon. The linear pressure dependence of K_T inherent in Murnaghan's equation may represent an adequate assumption for small bodies like the Moon and the satellites of the outer giant planets (see **Chapter 10.18** in this volume). However, even for planets in the mass and size range of Mercury or Mars, with central pressures of the order of the isothermal bulk modulus, more reliable higher-order finite-strain equations of state corrected for thermal pressure effects such as eqn [33] are recommended for the construction of models of the internal density distribution.

10.02.4 Earth as a Type Example of a Terrestrial Planet

Inferences about the structure, composition, and mineralogy of the planets are guided by our knowledge of the Earth. In some cases, Venus, for example, observational constraints on the interior are so minimal that the best we can do is to argue by analogy with Earth. Our knowledge of the Earth's interior, though partially based on the same types of observations available for the planets, rests largely on seismological data. The Moon is the only planetary body other than Earth for which we have seismological data, and those data are limited in both quality and quantity. The structure, composition, and mineralogy of the Earth are discussed at length in other volumes of this treatise (see **Chapter 1.08** and **Chapter 2.01**) and in *Treatise on Geochemistry*. The brief summary we present here is intended only to place the blurry pictures of planetary interiors in the context of the sharper picture of the Earth's interior.

10.02.4.1 General

The basic structure of the Earth is that of a three-layer sphere. The innermost layer is a metallic core of radius 3486 km. Surrounding the core is a rocky spherical shell or mantle of thickness 2885 km, and encircling the mantle is a thin rocky crust distinct in composition from the underlying mantle. The core is itself divided into two parts, an inner solid core of radius 1217 km surrounded by an outer liquid shell about 2269 km thick. It is believed that the inner core has formed as a consequence of the cooling of the Earth over geologic time, a process that has resulted in the partial solidification of the core from the inside out. The mantle is itself divided into two parts, the upper mantle about 660 km thick and the lower mantle about 2225 km thick. The mantle subdivisions are based on the occurrence of solid–solid phase transitions in the mantle rock, about which more is said in the succeeding text. The crust is uniform in neither composition nor thickness.

An ~6 km thick crustal layer covers the floors of the oceans, while a compositionally distinct crust of about 30 km thickness comprises the continents. The basic structure of the Earth is shown in **Figure 5**.

10.02.4.2 Interior Structure

The overall structure of the Earth is generally believed to have been set early in Earth's evolution, within tens to about 100 My after accretion was complete (see Volume 9, 'Evolution of the Earth'). The gravitational potential energy released upon accretion was large enough to melt the Earth's interior yielding liquid metal, mostly iron, that sank toward the center and accumulated to form the metallic core. The process of core formation could have begun before accretion was complete. Core formation itself releases additional energy that could have contributed to melting the mantle. Formation of the core could have been a runaway process. The timing of crustal formation is more uncertain. Certainly, oceanic crust (basalt) is being produced today by melting of mantle rocks at mid-ocean ridges. This process has occurred throughout Earth's history, as long as plate tectonics has been active. Basaltic volcanism does not require plate tectonics, as is evident from the surfaces

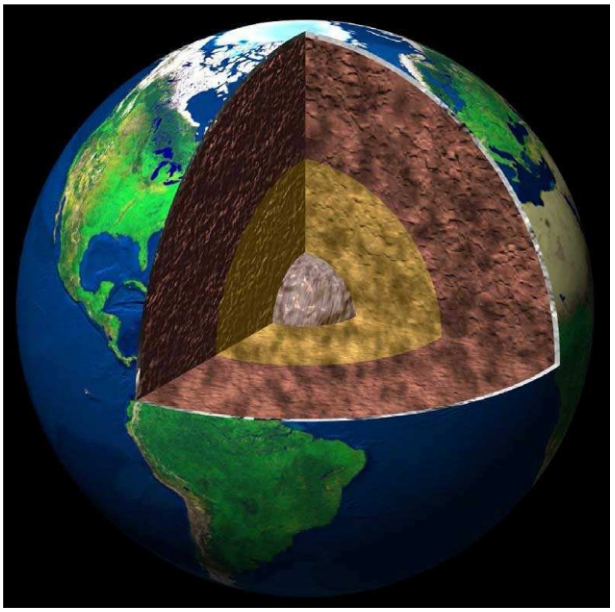

Figure 5 Cutaway view of the Earth's interior. © Calvin J. Hamilton.

of other planets, so basaltic crust was likely produced on Earth early in its evolution by plate tectonics or other processes. Oceanic crust is recycled back into the mantle by plate tectonics. The oldest oceanic crust on Earth is only about 200 My. The more difficult problem in crustal evolution is the history of the continental crust. The more siliceous continental crust is believed to have been produced by multiple stages of melting in the presence of water. The process is occurring in the andesitic volcanoes at convergent plate margins. The main question is how much continental crust existed on Earth as a function of time throughout Earth's history.

10.02.4.3 Composition

The bulk composition of the Earth, aside from its volatiles, is believed to be that of the meteorites classified as CI chondrites, the assumed primordial building blocks of the Earth. Accordingly, the Earth is 32.7 wt.% Fe, 15.4 wt.% Mg, 14.2 wt.% Si, 1.89 wt.% Ni, 1.71 wt.% Ca, and 1.59 wt.% Al (McDonough and Sun, 1995). Other elements are of course present in relatively smaller amounts. Much of the Earth's Fe and Ni have segregated into the core that contains about 87.5 wt.% Fe, 5.4 wt.% Ni, 0.95 wt.% Cr, 0.5 wt.% Mn, and unknown amounts of light elements (McDonough and Sun, 1995). In descending order by their significance, these elements are Si, S, O, H, and C (Poirier, 1994) (see **Chapter 2.06** in Volume 2 of this treatise). The light elements of the core are preferentially excluded from the inner core upon its solidification and concentrated in the liquid outer core. The major elements of the mantle rocks, aside from volatiles, are Mg (22.8 wt.%), Si (21.0 wt.%), Fe (6.26 wt.%), Ca (2.53 wt.%), and Al (2.35 wt.%) (McDonough and Sun, 1995).

The composition of the mantle is also constrained by its density, seismic velocities, seismic anisotropy, and the compositions of ophiolite complexes and mantle xenoliths brought to the surface by kimberlitic and alkali basaltic eruptions. The elements of the mantle are contained in the minerals olivine ($(Mg,Fe)_2SiO_4$), orthopyroxene ($(Mg,Fe)SiO_3$), clinopyroxene ($([Ca,Mg]_2,NaAl)Si_2O_6$), and garnet ($(Mg,Fe,Ca)_3Al_2Si_3O_{12}$). Olivine is a complete solid solution of Mg and Fe silicates with end-members fayalite (Fe_2SiO_4) and forsterite (Mg_2SiO_4). Orthopyroxene is a limited solid solution with magnesium end-member enstatite (the Fe end-member is unstable). Clinopyroxene is a pyroxene solid solution with Ca and Al. Among all possible rock assemblages of these minerals, only peridotites (olivine + pyroxene) and eclogites (pyroxene + garnet) are commonly found in mantle-derived samples. Eclogite is isochemical with basalt and transforms to basalt at depths of less than about 80 km in the Earth.

The mineralogy and composition of the Earth's mantle might be that of pyrolite, a peridotite model introduced in 1962 by Ringwood to explain the seismic, petrologic, and mineralogical properties of the upper mantle (Ringwood, 1975). To better understand the structure of the Earth's mantle, the olivine phase diagram obtained from experiments was of great importance (Akimoto and Fudisawa, 1968; Ringwood, 1970). This diagram allowed explanation of the boundaries between different layers in the mantle and provided constraints on the radial temperature distribution.

10.02.4.4 Mineralogy

Olivine and pyroxene transform to higher density polymorphs under the high temperatures and pressures encountered at depth in the Earth's mantle. At a depth of about 410 km, olivine transforms to spinel (the transformation occurs in two steps involving wadsleyite, or β-spinel, and at higher pressure ringwoodite, or γ-spinel). A prominent seismic discontinuity at the depth of about 410 km is believed associated with the olivine–spinel phase change. This subsolidus phase change is exothermic and involves jumps in seismic velocities and density. Another major seismic discontinuity occurs at the depth of about 660 km, and this is believed to coincide with the transformation of ringwoodite to magnesium perovskite and magnesiowüstite. This solid–solid phase transformation is endothermic. The region between 410 and 660 km depth is known as the transition zone. The depth of 660 km marks the boundary between the upper mantle and the lower mantle. Perovskite-forming reactions also occur in the pyroxene system but over a wider pressure interval than in the olivine system. Garnet, for example, dissociates to form $MgSiO_3$ and $CaMgSiO_3$ perovskites plus Al_2O_3. The lower mantle is thus dominated by silicate perovskites.

Recent laboratory and theoretical results have demonstrated that perovskite transforms to still another structure, postperovskite, at pressures and temperatures found just above the core–mantle boundary in the Earth (Murakami et al., 2004; Oganov and Ono, 2004; Tsuchiya et al., 2004). The perovskite–postperovskite transformation, like the olivine–spinel phase change, is an exothermic reaction. The location of this phase transition is coincident with the several hundred kilometer thick layer at the bottom of the mantle known as the D" layer wherein seismic velocities undergo large variations (Lay et al., 2005).

The subsolidus phase changes in the Earth's mantle have important effects on the dynamics of the mantle (Schubert et al., 2001). The exothermic reactions generally promote convection, while the endothermic phase change retards it. Do similar phase changes occur in other terrestrial planets? Venus is large enough that the olivine–spinel and spinel–perovskite phase changes should be present in its mantle. However, the pressure at the base of the Venusian mantle may not be sufficiently high for the occurrence of the perovskite–postperovskite phase change. Mars is so small that only the olivine–spinel phase change might occur near the base of its mantle. Possible phase changes in the mantles of the other planets will be discussed in more detail in the succeeding text.

10.02.5 Vesta

NASA's Dawn spacecraft orbited the asteroid 4 Vesta for about a year returning valuable information about its surface and interior. Vesta, formally known as 4 Vesta, is the second-largest asteroid in the solar system (**Figure 6**). Vesta's shape is approximated by a triaxial ellipsoid with dimensions 286.3, 278.6, and 223.2 km; its mean radius is 262.7 km (Russell et al., 2012). Prior to the arrival of the Dawn spacecraft at Vesta, the asteroid was considered to be a differentiated protoplanet with

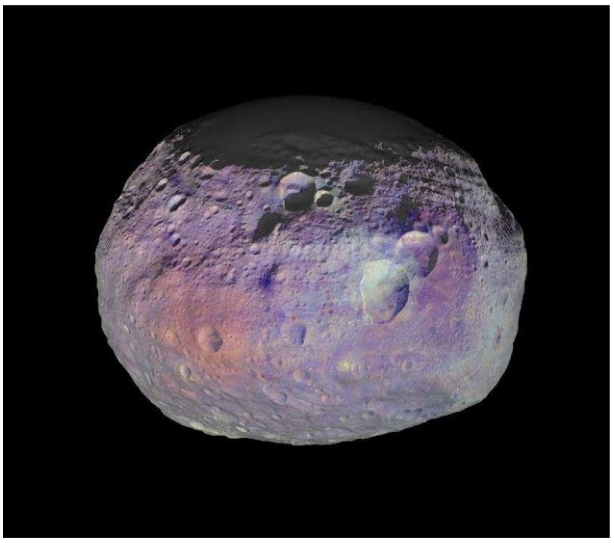

Figure 6 Image of Vesta captured by the Dawn spacecraft (PIA15506). The surface mineralogy of Vesta (colorized) indicates a complex magmatic evolution in the course of internal differentiation and crust formation. © NASA/JPL–Caltech/UCLA/MPS/DLR/IDA/PSI.

an iron core that survived essentially intact from the earliest stages of solar system formation (Kleine et al., 2009; Righter and Drake, 1997). This view was based on the identification of 4 Vesta as the source of the howardite–eucrite–diogenite (HED) meteorites. All the data acquired by Dawn are consistent with this paradigm.

The mass and average density of Vesta are 2.59×10^{20} kg and 3456 kg m^3, respectively (Russell et al., 2012). The average density of Vesta, combined with its measured second-degree gravitational moment $J_2 = 0.03178$ (Russell et al., 2012) and reasonable assumptions about iron core density in a two-layer model, leads to values of core radius and core mass fraction of about 110 km and 18%, respectively, consistent with estimates from analyses of HED meteorites (Russell et al., 2012). Based on its shape, size, mean density, and rotation rate ($1617.333^\circ\,day^{-1}$), it is unlikely that Vesta is in hydrostatic equilibrium.

The surface mineralogy of Vesta is similar to the composition of the HED meteorites, confirming that Vesta's crust formed by melting of a chondritic parent body. Vesta is scarred by a giant impact basin, Rheasilvia, at its south pole. The basin is about 500 km in diameter and about 19 km deep. It has a large central peak almost as high as Olympus Mons on Mars. Rheasilvia obliterated about half of an older 400 km south polar basin, Veneneia (Schenk et al., 2012). Both basins are geologically young, about 1–2 billion years. The volume of material excavated by these impacts is sufficiently large to produce the Vesta-family asteroids (vestoids or asteroids with orbits and reflectance spectra similar to Vesta) and the HED meteorites.

These impacts produced a strong dichotomy between the northern and the southern hemispheres of Vesta, reflected in surface albedo and crater densities. Vesta's early differentiation of an iron core was likely caused by the heating of the short-lived radioactive isotopes ^{26}Al and ^{60}Fe. The half-lives of these rapidly decaying elements place a tight constraint on the timing of the formation of Vesta. The discovery of remanent magnetization in the Millbillillie eucrite and ALH 81001 (Fu et al., 2012) suggests the existence of an early dynamo on their parent body 4 Vesta.

10.02.6 The Moon

The knowledge of the lunar interior is one of the key elements to a better understanding of the formation and evolution of the solar system. The earliest history of the Moon together with the first billion years of the impact history of the Earth–Moon system is partly retained in the subsurface structure and surface geologic record of the Moon. Dynamic modeling and isotopic data suggest that the accretion and differentiation of the Moon occurred soon after the formation of a vapor and debris cloud caused by the giant impact of a Mars-sized planetesimal into the early Earth (Canup and Asphaug, 2001). The chronology of major impact events has been derived from rock and soil samples collected during the Apollo and Luna missions and represents the current best database for dating other planetary surfaces in the solar system (Kaula et al., 1986). A number of lunar meteorites provide additional constraints on the early evolution and bulk composition of the lunar crust (Korotev, 2005).

10.02.6.1 General

The low mean lunar density of 3344 kg m^{-3} suggests that the Moon is depleted in iron relative to the Earth and any other terrestrial planet. Despite seismic measurements at the Apollos 12, 14, 15, and 16 landing sites and improved values of the MoI and tidal potential Love number, models of the lunar interior are nonunique. Some uncertainty is still connected with the radius and physical state of a small iron core, the possible existence of an inner solid core, more gradual or discontinuous seismic velocity variations within the lunar mantle, and lateral and vertical heterogeneities of the lunar crust. There is a pronounced dichotomy between the crustal thicknesses of the lunar nearside and farside as a consequence of the early differentiation of the Moon, possibly augmented by variable heat transfer in the molten lunar interior and large-scale insulation due to the formation of a protocrust and subsequent deposition of thick impact ejecta (Jolliff et al., 2000b). The internal differentiation of the Moon was accompanied by the formation of a magma ocean subsequent to hot accretion and extraction of a highly aluminous flotation crust enriched in plagioclase feldspar (Smith et al., 1970; Warren, 1985; Wood et al., 1970). The duration and depth of differentiation during the magma-ocean phase, the possible existence of an undifferentiated lower mantle, and the mechanism of core formation are among the key questions of lunar science (Jolliff et al., 2000b). For review articles on the geophysics, geochemistry, and geology of the Moon, we refer the reader to Wieczorek et al. (2006), Shearer et al. (2006), and Jaumann et al. (2012), respectively.

10.02.6.2 Interior Structure

The Clementine and LP missions have returned the first global data sets of lunar gravity, topography, remanent magnetism,

mineralogy, and chemical composition of the lunar surface (Binder, 1998; Nozette et al., 1994). Global models of lunar topography have improved considerably in terms of spatial resolution and accuracy, when precise laser altimetry-based maps became available on Clementine (Zuber et al., 1994), Kaguya (SELENE) (Araki et al., 2009), and Lunar Reconnaissance Orbiter (Scholten et al., 2012; Smith et al., 2010). From Doppler tracking of the LP (Konopliv et al., 2001), 4-way Doppler tracking of the Kaguya (SELENE) spacecraft (Namiki et al., 2009), and spacecraft-to-spacecraft tracking observations of the dual Gravity Recovery and Interior Laboratory (GRAIL) spacecraft (Zuber et al., 2013), the global gravitational field of the Moon has been recovered with steadily increasing spatial and temporal resolution.

From LP Doppler data, Konopliv et al. (1998, 2001) had obtained basic information on the gravitational field of the Moon and improved values of the Moon's mass ($GM = 4902.801076 \pm 0.000081$ km^3 s^{-2}, with G the gravitational constant), mean MoI factor ($I/MR^2 = 0.3931 \pm 0.0002$), and tidal potential Love number ($k_2 = 0.026 \pm 0.003$). Based on a combined analysis of satellite tracking data from Lunar Orbiters I–V, the Apollo 15 and 16 subsatellites, Clementine, LP, and some SMART-1 spacecraft tracking data, Goossens and Matsumoto (2008) derived a lower value of $k_2 = 0.0213 \pm 0.0075$, in good agreement with determinations from lunar laser ranging. The tidal response of the Moon indicates that the deep lunar interior is still sufficiently hot to retain partially molten rock and a fluid core. However, prior to Kaguya (SELENE), the resolution of global gravity field solutions had been limited by the lack of tracking data within 60° of the center of the lunar farside. The first gravity maps revealing the unknown subsurface structures of the lunar farside were accomplished by using two satellites in coplanar orbits, with one satellite placed in a high orbit as a relay satellite between the main orbiter and the Earth and a VLBI subsatellite for differential tracking of the relay satellite (Namiki et al., 2009). The 4-way Doppler measurements of Kaguya (SELENE) allowed an estimation of the global medium- to-short-scale gravitational field of the Moon up to degree 70 without invoking unproven a priori constraints (Matsumoto et al., 2010).

The GRAIL primary mission has improved globally the precision of the gravity spectrum by up to three or four orders of magnitude since previous gravity field determinations were mostly limited to the lunar nearside (Konopliv et al., 2013; Lemoine et al., 2013). As a consequence, present knowledge of the lunar low-degree field has improved considerably and factors directly into more accurate solutions for the degree-2 and degree-3 tidal potential Love numbers k_2 and k_3. Whereas Konopliv et al. (2013) deduced $k_2 = 0.02405 \pm 0.00018$ and $k_3 = 0.0089 \pm 0.0021$, Lemoine et al. (2013) determined $k_2 = 0.024615 \pm 0.0000914$ and a preliminary value of $k_3 = 0.00734 \pm 0.0015$, illustrating the present level of inherent uncertainty of the different gravity estimation techniques applied.

Lunar laser ranging data show that the true spin axis of the Moon is displaced from the Cassini alignment (mean direction of the spin axis) by 0.26 arcsec, possibly caused by internal dissipation in the presence of partially molten rock and a fluid core (Dickey et al., 1994; Williams et al., 2001; Yoder, 1981). Magnetic field measurements were made by small satellites left in lunar orbit by the Apollo 15 and 16 missions. Although localized regions of magnetized rock were detected by the subsatellites, no global lunar magnetic field could be measured. A lunar magnetic dipole moment can be no larger than 10^{16} A m^2, that is, about seven orders of magnitude smaller than the Earth's dipole moment. The absence of a present-day global lunar magnetic field can be explained by the absence of an active lunar core dynamo. However, the paleomagnetic record of some lunar samples suggests the former existence of a significant magnetic field produced by dynamo action in a liquid metallic core (Hood and Jones, 1987). A convectively driven lunar dynamo might not be expected to last more than a few hundred million years until convection in the core has ceased. If the lunar dynamo lasted for a longer period of time, other mechanisms, such as precession (Dwyer et al., 2011) and compositional convection due to inner core freeze out, must be invoked to explain long-lived dynamo action. The recent detection of strong magnetization in a mare basalt sample indeed suggests the former existence of a relatively long-lived lunar core dynamo that may have operated between 4.2 and 3.7 billion years ago (Shea et al., 2012).

The Clementine topographic and gravity maps of Zuber et al. (1994) were the first reliable global characterizations of surface elevations and the gravitational field of the Moon. On the basis of those data, the lunar highlands appeared to be nearly isostatically compensated; however, basin structures showed a wide range of compensation states independent of their sizes or ages (Zuber et al., 1994). Beneath all resolvable basin structures, Zuber et al. (1994) observed crustal thinning and concluded that the structure and thermal history of the Moon are more complex than previously assumed. The GRAIL tracking observations have allowed the construction of the global gravitational field up to degree and order 660 (Konopliv et al., 2013; Lemoine et al., 2013), revealing a number of tectonic-, volcanic-, and impact-related geologic features not resolved in previous gravity maps. In particular, topographic features preserved in the highly fractured lunar crust apparently predominate the gravitational signature in the mid- to high-degree field up to degree and order 420 (Zuber et al., 2013). Using gravity gradiometry on the GRAIL observations, a globe-encircling population of long and elongated positive gravity anomalies has been detected, which are interpreted in terms of vertical sheetlike intrusions of solidified melt at depth indicative of lithospheric extension. The distribution, orientation, size, and stratigraphy of these linear subsurface features or dikes suggest that early in lunar history, the Moon experienced a state of thermally induced global extension by 0.6–4.9 km in radius (Andrews-Hanna et al., 2013). Therefore, the new high-resolution gravitational field data are also informative of improved thermal evolution models of the Moon.

Previous estimates of the crustal thickness varied from 30 to 35 km under basins associated with mass concentrations (mascon basins) to 90–110 km beneath the highlands, whereas irregular maria have intermediate thickness values of 50–60 km (Bills and Ferrari, 1977). From a reanalysis of gravity data acquired by the Apollo and Clementine spacecraft and assuming a thickness of 55 km at the Apollo 12/14 site, the thickness of the lunar farside crust has been estimated at 67 km, resulting in a mean thickness of 61 km if a uniform

crustal composition is assumed (Neumann et al., 1996). Analysis of global gravity and topography data implies that the thickness of the farside crust exceeds that of the nearside by about 15 km on average (Wieczorek et al., 2006). Nevertheless, the gravity-based results are model-dependent, and it is possible to construct models without large differences in crustal thickness between the nearside and the farside hemispheres. A difference in crust thickness between nearside and farside is thought to contribute substantially to the 1.7 km offset of the center of mass relative to the center of figure of the Moon in the direction of Earth (Hood and Jones, 1987; Kaula et al., 1974; Zuber et al., 1994). Wieczorek and Phillips (1998) had computed a variety of crustal thickness maps for the Moon, assuming both homogeneous and dual-layered crusts. The homogeneous crust model characterized by a constant crustal density provides a total crust thickness of 66 km, whereas the preferred dual-layered model of the lunar crust consisting of a 31 km thick upper crust and a 29 km thick lower crust yields a total thickness of 60 km. The gravitational field measurements of the LP spacecraft suggest a mean crustal thickness of about 70 km assuming Airy compensation of the lunar highlands (Konopliv et al., 1998) (see **Chapter 10.05** in this volume).

Early seismic studies favored crustal thickness of about 60 km beneath the Apollo network (Goins et al., 1981; Nakamura et al., 1982; Toksöz et al., 1974). An early analysis of body wave phases from artificial impacts of known impact time and location provided evidence for a dual-layered crust about 60 km thick beneath the Apollo 12 and 14 stations near Mare Cognitum (Toksöz et al., 1974), whereas a putative thickness of 75 ± 5 km was derived from seismic data near the Apollo 16 highland site (Goins et al., 1981). More recent studies, however, favor thinner crusts of only 45 km (Khan et al., 2000), 38 km (Khan and Mosegaard, 2002), or 30 km (Gagnepain-Beyneix et al., 2006). Chenet et al. (2006) attributed travel time variations observed from impact events to crustal thickness variations at impact sites and obtained thicknesses between 30 and 40 km at most sites that are also compatible with gravity field data. The mean thickness of the lunar crust is estimated as 49 ± 15 km if an Airy-type compensation mechanism (hydrostatic balance between crust and more dense mantle) applies (Wieczorek et al., 2006). A bulk density of the lunar highlands crust of 2550 kg m^{-3}, substantially lower than previously thought, has been inferred from the GRAIL high-resolution gravity data and suggests an average crustal porosity of 12% to depths of at least a few kilometers (Wieczorek et al., 2013). Furthermore, these authors find that the low bulk crustal density can be used to construct a global crustal thickness model in agreement with the Apollo seismic constraints and that the bulk refractory element composition of the Moon is not required to be enriched relative to that of Earth in case of a thin lunar crust with a mean thickness between 34 and 43 km.

Whereas early determinations of the MoI factor (Konopliv et al., 1998) are consistent with a core radius between 220 and 450 km, independent observations of the lunar magnetic moment induced in the geomagnetic tail of the Earth suggest that the lunar core radius is 340 ± 90 km (Hood et al., 1999). Using electromagnetic sounding methods, Shimizu et al. (2013) deduced estimates of the electrical conductivity of the lunar mantle and the size of the lunar core from Kaguya (SELENE) magnetic field data. The core radius is related to the ratio between the induced and inducing magnetic dipole moments and estimated to be 290 km with an upper bound of about 400 km (95% confidence limit) (Shimizu et al., 2013). Based on the knowledge of the Moon's mean density and MoI factor as derived from LP data and the tidal potential Love number k_2 and quality factor Q as obtained from the entire set of lunar laser ranging data, Khan et al. (2004) obtained information on the radial distributions of density and seismic velocities. The resultant structural model suggests the presence of a molten or partially molten iron core with radius and density of about 350 km and 7200 kg m^{-3}, respectively (Khan et al., 2004). A recent reprocessing of the Apollo seismic data that once allowed the existence of a lunar core with a radius of 170–360 km (Nakamura et al., 1974) supports not only the presence of a partially molten mantle layer above a liquid core with a radius of 330 km but also the possible existence of a small solid inner core (Garcia et al., 2011; Weber et al., 2011). The possible range of density models that simultaneously satisfy the mean density and MoI of the Moon is shown in **Figure 7**.

10.02.6.3 Composition

The lunar surface is divided into light-colored heavily cratered highlands and smooth dark lowland maria, which are most prominent on the nearside. The circular maria are frequently associated with mass concentrations (mascon basins) causing a positive anomaly in the lunar gravity field due to the larger density of the basalt layer compared to that of the surrounding anorthositic crust. Uplift of the crust–mantle interface provides another contribution to the positive gravity anomaly. Some mascon basins that do not appear to be associated with mare volcanism are known (Konopliv et al., 1998, 2001). Neumann et al. (1996) and Wieczorek and Phillips (1999) had suggested that the lunar mascons might partly result from superisostatic uplift of the crust–mantle interface. The highlands are

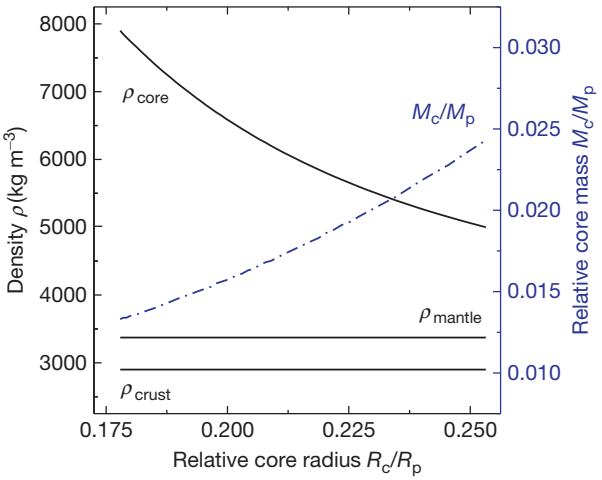

Figure 7 Three-layer model determinations of lunar mantle and core density and core mass fraction M_c/M_p versus relative core radius R_c/R_p consistent with the mean density and moment of inertia factor of the Moon (MoI = 0.3931). The thickness and density of the anorthositic lunar crust are fixed at 60 km and 2900 kg m^{-3}, respectively.

saturated with large craters owing to their greater age in comparison with the maria and dominate the lunar farside and most of the nearside. Highly anorthositic rocks are exposed in the lunar highlands, whereas the maria represent floods of basaltic lava that were erupted about ~0.5 Gy after major impact events. Little mare volcanism is associated with the South Pole–Aitken basin, and Oceanus Procellarum, the largest expanse of mare volcanism, is not necessarily associated with an impact event (Neumann et al., 1996).

The range of chlorine isotope compositions of Apollo basalts and glasses is attributed to volatile release of metal halides during volcanic eruptions, suggesting that the lunar interior is almost anhydrous with hydrogen concentrations reduced by a factor of $\sim 10^4$–10^5 as compared to Earth's (Sharp et al., 2010). This is consistent with a collisional origin of the Moon that predicates a substantial lack of water or hydrogen in the lunar interior (Canup and Asphaug, 2001). This view has been challenged, however, by the recent detection of mineral-bound water by applying highly sensitive analytic techniques to volcanic glasses (Hauri et al., 2011; Saal et al., 2008) and OH^+-bearing apatite minerals in lunar samples to infer the hydrogen content and isotopic composition in terms of D/H ratios (Boyce et al., 2010; Greenwood et al., 2011; McCubbin et al., 2010b). These estimates range from (i) a lunar mantle water content similar to that of the Earth's mantle; to (ii) 'wet' conditions, but at much lower water abundances, and D/H ratios compliant with some cometary water present in the lunar interior; to (iii) terrestrial-like original values subject to fractionation due to outgassing and thereby resulting in elevated D/H ratios (e.g., Jaumann et al., 2012, and references therein). In the absence of lithospheric plate recycling, however, it is difficult to explain the entrainment of cometary water into the lunar mantle. The issue of the volatile inventory of the lunar interior remains unresolved at this point but will benefit from steadily improving laboratory instrumentation and analytic techniques.

It appears that the majority of the lunar basalts erupted within the Procellarum KREEP Terrane (Jolliff et al., 2000a), a unique geologic province that contains elevated abundances of heat-producing elements. Wieczorek and Phillips (2000) had shown that the enhanced heat production of this province could have melted the underlying mantle. Wieczorek et al. (2001) had suggested that mare basalts might preferentially erupt within the impact basins since mare basalts are more dense than the upper anorthositic crust but less dense than the deep, more mafic, lower crust. If an impact event stripped away the upper crust, mare basalts could easily rise through the crust and erupt based solely on buoyancy considerations. The compositions of the mare basalts are consistent with volcanic source regions of several hundred kilometers in depth (Heiken et al., 1991). Mare basalt samples provide an assessment of the Mg number MgO/(MgO + FeO) of 0.75–0.8 and a bulk Al_2O_3 content of <1 wt.% for the upper mantle (Hood and Zuber, 2000). The ages of the basaltic maria, as determined from returned samples and careful crater chronological studies, range between about 4 and ~1.2 Gy (Hiesinger et al., 2003) and suggest that U-, Th-, and K-rich residua of the crystallized magma ocean providing the heat required for mantle melting were at least locally present (Jolliff et al., 2000a; Wieczorek and Phillips, 2000). The lateral and depth variations of crustal composition have been assessed from compositional mapping of central peaks (Wieczorek and Zuber, 2001) and ejecta blankets of large impact basins (Bussey and Spudis, 2000). Deeply excavated ejecta are found to be more mafic than the surface material (Pieters and Tompkins, 1999).

10.02.6.4 Mineralogy

The Moon is the only planetary body other than the Earth for which a seismic velocity structure has been derived from analyses of the Apollo seismic data set (see **Chapter 10.03** in this volume). A seismic network of four stations on the lunar nearside, installed at the landing sites of Apollos 12, 14, 15, and 16 from 1969 to 1972, continued to operate until it was turned off in September 1977. With few exceptions, almost all seismic events within the Moon occurred on the nearside (Nakamura, 2005). The seismic activity of the Moon is provided by deep moonquakes located at 850–1000 km depth, shallow moonquakes, or high-frequency teleseismic events situated at 50–220 km depth and meteoroid impacts onto the lunar surface. The deep moonquakes, apparently confined to the lunar nearside, are most numerous and triggered by tidal deformation of the Moon. More than 12 000 events associated with 81 identified sources ('nests') were recorded during the lifetime of the Apollo seismic network. During the limited operational period of the lunar seismic network with stations on the near-Earth hemisphere, only one meteoroid event was detected with seismic rays crossing a central low-velocity zone from which the size of a lunar core was estimated for the first time. Early seismic analyses were based on a limited set of arrival time readings (Goins et al., 1981), whereas the model of Nakamura (1983) employs the complete data set of 5-year simultaneous operation of four Apollo seismometers including more deep moonquake sources. More detailed lunar velocity and density structure models have been obtained from a new inversion of different subsets of the Apollo seismic data set by applying various inversion techniques to revised arrival time readings and seismological array techniques (Chenet et al., 2006; Garcia et al., 2011; Khan and Mosegaard, 2002; Khan et al., 2000, 2004; Lognonné et al., 2003; Weber et al., 2011).

The Apollo seismic data record indicates that the chemical composition of the silicate mantle is consistent with that of an olivine–pyroxene mixture (Hood and Jones, 1987; Toksöz et al., 1974). The seismic velocities are almost constant in the upper mantle and more heterogeneously distributed in the middle mantle below. The most prominent increase in seismic velocity at a depth of ~500 km below the surface of the Moon represents the transition from the upper mantle to the middle mantle (**Figure 8**). Nevertheless, recent analyses do not require a discontinuity at this depth (Khan et al., 2007). If this discontinuity exists and is global in extent, it may represent the initial depth of melting and differentiation during the magma-ocean phase of the Moon. If it is only present on the nearside hemisphere, it might instead reflect the maximum depth of melting of the mare basalt source region underneath the Procellarum KREEP Terrane (Wieczorek and Phillips, 2000).

This discontinuity has been interpreted in terms of a mineralogical phase transition from the spinel to the garnet stability field. Alternatively, a change in composition to more aluminous and MgO-rich mafic silicates has been invoked,

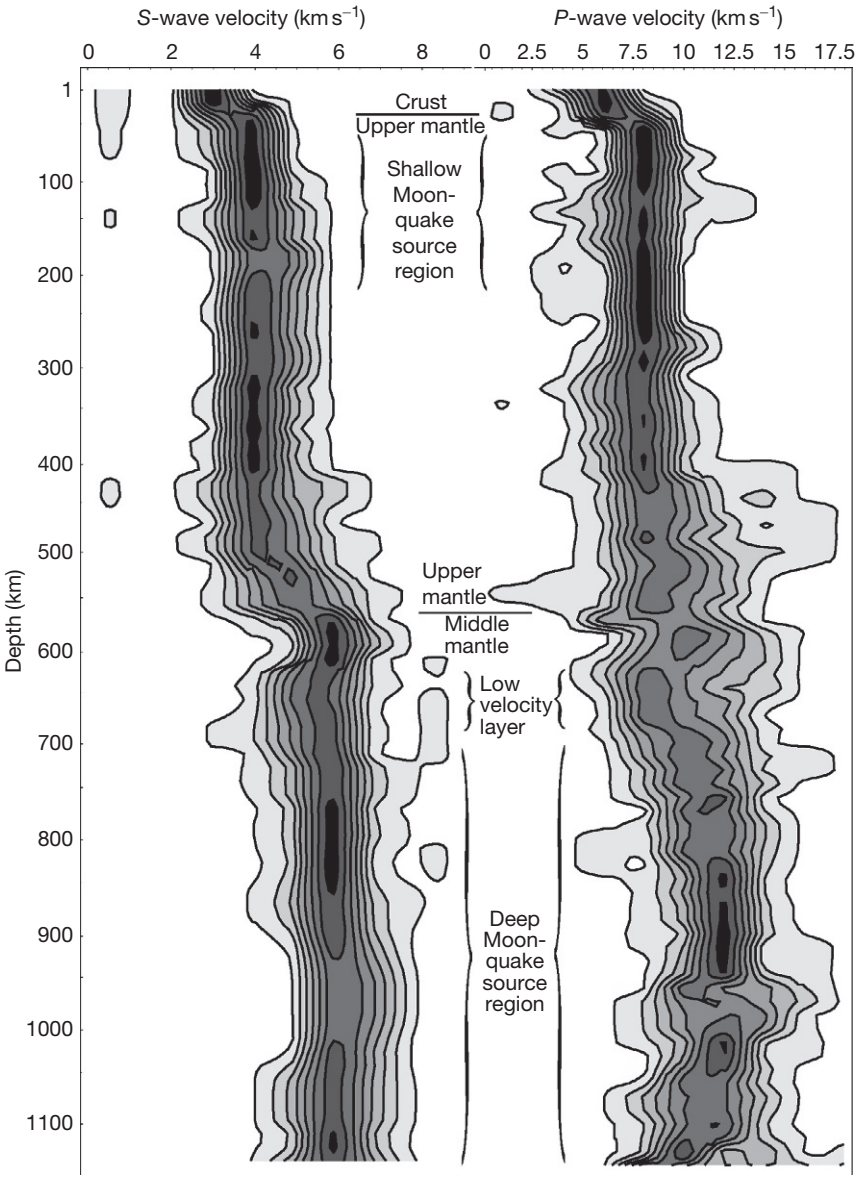

Figure 8 Marginal posterior probability distributions illustrating the range of possible (left) *S*-wave and (right) *P*-wave velocity structures of the Moon based on a total number of 50 000 models. The contour lines define nine equally sized probability density intervals for the distributions. Note that maximum probability does not necessarily correspond to maximum likelihood of a calculated velocity. Adapted from Khan A and Mosegaard K (2002) An inquiry into the lunar interior: A nonlinear inversion of the Apollo lunar seismic data. *Journal of Geophysical Research* 107(E6), http://dx.doi.org/10.1029/2001JE001658, with permission American Geophysical Union; Copyright 2002.

thereby increasing the Mg number below this depth (Khan et al., 2006; Nakamura, 1983). The reanalysis of the Apollo lunar seismic data indicates a homogeneous, constant-velocity upper mantle extending down to 560 ± 15 km depth, whereas the radial velocity distribution suggests more inhomogeneous middle and lower mantle layering (Khan and Mosegaard, 2002; Khan et al., 2000). The compositional change across the discontinuity together with the homogeneity of the upper mantle and the inhomogeneity of the middle mantle has been interpreted in terms of the initial depth of melting and differentiation during the magma-ocean phase of the Moon (Hood and Zuber, 2000). Based on mare basalt petrology and thermal evolution considerations, Elkins-Tanton et al. (2003a) identified the 500 km discontinuity with the maximum depth of melting beneath the Procellarum KREEP Terrane on the lunar nearside. It is also possible that the 500 km discontinuity represents stratified olivine- and orthopyroxene-rich cumulates that were subsequently emplaced at the bottom of the lunar magma ocean. The mineralogical layering is supported by seismic inversions that account for thermodynamic mineral phase equilibriums (Kuskov, 1995, 1997; Kuskov and Fabrichnaya, 1995; Kuskov and Kronrod, 1998).

In the lower mantle below a depth of about 1150 km, seismic waves are strongly attenuated. This has been interpreted in terms of a partial melt zone that extends down to the core–mantle boundary (Nakamura, 2005; Weber et al.,

2011). Because of the depth distribution of the deep moonquakes, the *P*- and *S*-waves do not sample depths below 1200 km, and thus, the core region remains poorly understood. Only one among the ~1700 meteoroid impacts occurred sufficiently distant to facilitate investigations of the deepest lunar mantle. This observation constrained the lunar core radius to a value between 170 and 360 km (Nakamura et al., 1974). Weber et al. (2011) used seismological array techniques to identify reflected phases from the deep interior of the Moon not resolved previously. These results are consistent with the existence of a partial melt layer in the deep mantle, a liquid iron-rich core, and a solid inner core, commensurate with previous studies using different data sets. The thicknesses of these layers, but not the overall structure, are subject to inherent uncertainties connected to the poorly known mantle structure, since the travel times of the new seismic phases are sensitive to the average propagation velocities within the mantle. The radius of the outer core has also been constrained by the detection of ScS phases in a set of carefully chosen recordings from sources with favorable orientation (Garcia et al., 2011).

10.02.6.5 Future Exploration

Considering the ambiguity inherent in the Apollo lunar seismic data, first reliable recordings of seismic phases traveling through the central region of the Moon must be expected from future landed missions. Models of the internal structure of the Moon would greatly benefit from the joint analysis of the lunar gravity field, topography, rotational state, tidal distortion, and orbital parameters combined with inversions of the entire record of lunar laser ranging, magnetic induction, and seismic data (Wieczorek et al., 2006; Williams, 2007). There are many open questions regarding the present constitution, origin, and evolution of the Moon that would be best addressed in the frame of a geophysical network mission (Mocquet et al., 2011). A higher temporal resolution and precision compared to ground- and orbit-based techniques alone can be achieved by emplacement of a geophysical network of one or several soft-landed surface stations on the Moon. The Apollo legacy suggests that geophysical network data could help improve the present knowledge of the Moon's interior structure, the lunar environment, and the dynamics of the Earth–Moon system.

10.02.7 Mercury

The planet Mercury is unique among the terrestrial planets in many respects. It represents an end-member of the terrestrial planets with respect to its density and distance from the Sun and thereby provides important constraints on planetary formation and evolution in the innermost part of the solar nebula (Balogh and Giampieri, 2002; Solomon, 2003; Strom, 1987).

10.02.7.1 General

Mercury is 4880 km in diameter, roughly 1/3 the size of Earth, and occupies only about 6% of the volume of Earth. Albeit substantially smaller in size, Mercury's surface gravity of 3.7 m s^{-2} is like that of the larger planet Mars. In 1974 and 1975, the Mariner 10 spacecraft provided the first close-up look of the planet during three encounters. From these flybys, better values of the planet's mass, mean radius, and average density were obtained. Less than half of the surface was covered by images at an average resolution of 1 km and < 1% at 100–500 m resolution, resulting in a limited characterization of surface morphology and geologic evolution. Among the most important findings of the Mariner 10 spacecraft was the then unexpected detection of a magnetic field of internal origin (Ness, 1979).

Our knowledge of Mercury from the Mariner flybys of the mid-1970s has now been superseded by newer observations of the planet, especially by the MESSENGER spacecraft that went into orbit around Mercury on 18 March 2011. Prior to orbit insertion, MESSENGER flew by Mercury three times and each of these flybys contributed substantially to our knowledge of the planet. Even before MESSENGER, our understanding of Mercury took a large step forward when radar observations of its surface from Earth succeeded in measuring Mercury's obliquity and the relatively large amplitude of the longitudinal librations of its rotation axis. These measurements, when combined with the Mariner 10 determination of Mercury's gravitational coefficient $C_{2,2}$, required that Mercury's core and mantle are decoupled by at least a partially molten core. The existence of a partially molten core lends strong support to the hypothesis that Mercury's magnetic field is produced by an active core dynamo.

The surface of Mercury is covered by densely cratered regions, intercrater plains, and smooth plains. The heavily cratered areas are some of the oldest surfaces in the solar system. Intercrater and smooth plains were likely emplaced volcanically though some could have formed of impact melts or other basin ejecta that behaved fluidlike upon deposition (Wilhelms, 1976). Lobate scarps and widespread volcanic plains suggest an early evolution in which volcanically induced expansion preceded a phase of planetary contraction (Solomon, 2003). Observations of Mercury's surface by the MESSENGER spacecraft have extended the Mariner 10 coverage to essentially the entire planet and provide a global view of Mercury's impact, tectonic, and volcanic history. Crater densities suggest that the smooth plains within and around the Caloris Basin, the largest impact basin on Mercury, are younger than intercrater plains elsewhere (Fassett et al., 2011; Strom et al., 2011). Even the most densely cratered regions on Mercury are deficient in craters between 20 and 100 km in diameter compared with the Moon, possibly as a consequence of early volcanic resurfacing (Fassett et al., 2011). For craters larger than 100 km in diameter, crater density on Mercury in a given size range is similar to that of the Moon.

Lobate scarps are the dominant tectonic landform on Mercury, and according to MESSENGER observations, they record a total contractional strain of at least one-third greater than inferred from Mariner 10 images (Solomon et al., 2008). The scarps must have formed at the end of or subsequent to the early phase of severe bombardment on Mercury because they sometimes pass through and deform old craters. The scarps may be a consequence of the cooling and contraction of the core, and if so, they are unique surface features that distinguish Mercury with its large core from the Moon with only a very small core.

MESSENGER observations have revealed that volcanism has played an important role in shaping Mercury's surface (Head et al., 2011). A large contiguous expanse of smooth plains covers much of Mercury's high northern latitudes. More than 6% of Mercury's surface is blanketed by these smooth volcanic plains. They embay other landforms, are distinct in color, and show several flow features. They partially or completely bury impact craters, whose sizes indicate plains thicknesses of more than 1 km and multiple phases of emplacement. These characteristics suggest emplacement in a flood-basalt style, consistent with x-ray spectrometric data indicating surface compositions intermediate between those of basalts and komatiites. Crater densities on the plains show that they formed after the Caloris impact basin, confirming that volcanism was a globally extensive process in Mercury's post-heavy bombardment era (Head et al., 2011).

High-resolution MESSENGER images of Mercury's surface reveal that many bright deposits within impact craters show fresh-appearing, irregular, shallow, rimless depressions or hollows (Blewett et al., 2011). The hollows are tens of meters to a few kilometers across, and many have high-reflectance interiors and halos. The host rocks are associated with crater central peaks, peak rings, floors, and walls. The most likely formation mechanisms for the hollows involve recent loss of volatiles through some combination of sublimation, space weathering, outgassing, or pyroclastic volcanism (Blewett et al., 2011). These features support the inference that Mercury's interior contains higher abundances of volatile materials than predicted by most scenarios for the formation of the planet (Blewett et al., 2011).

The neutron spectrometer (Lawrence et al., 2013) and the laser altimeter (Neumann et al., 2013) instruments on the MESSENGER spacecraft have found evidence of water ice and other deposits in permanently shadowed craters at Mercury's north pole. The first indication that there might be ice at Mercury's poles came from Earth-based measurements of radar-bright regions near Mercury's north and south poles (Slade et al., 1992). Subsequent measurements showed that these unusual radar characteristics are confined to permanently shadowed regions within high-latitude impact craters (Harmon et al., 2011). The leading explanation for the high radar reflectance is the presence of large amounts of water ice that can be thermally stable in regions of permanent shadow over geologically long periods of time (Harmon et al., 2011). The MESSENGER neutron spectrometer measured enhanced concentrations of hydrogen, both at the surface in permanently shadowed craters and sometimes buried beneath other deposits, consistent with pure water ice. The MESSENGER laser altimeter observed surface reflectance anomalies over permanently shadowed poleward-facing slopes near Mercury's north pole that are spatially collocated with areas of high radar backscatter thought to be due to near-surface water ice. The total mass of water at Mercury's poles is inferred to be 2×10^{13}–10^{15} kg and is consistent with delivery by comets or volatile-rich asteroids (Lawrence et al., 2013). Both Mercury and the Moon (Mitrofanov et al., 2010) have preserved water ice at their poles.

The major element composition of Mercury's surface has been measured by the x-ray spectrometer on MESSENGER (Nittler et al., 2011). The x-ray fluorescence spectra show that Mercury's surface has a different composition from the surfaces of other terrestrial planets. Relatively high Mg/Si and low Al/Si and Ca/Si ratios rule out a lunar-like feldspar-rich crust. Mercury's ratios are intermediate between typical basaltic compositions and more ultramafic compositions comparable to terrestrial komatiites (Nittler et al., 2011). The sulfur abundance is at least ten times higher than that of the silicate portion of the Earth or the Moon, and this observation, together with a low surface Fe abundance, supports the view that Mercury formed from highly reduced precursor materials, similar perhaps to enstatite chondrite meteorites or anhydrous cometary dust particles (Nittler et al., 2011), and the planet's core might contain Si as well as sulfur (Malavergne et al., 2010).

The MESSENGER gamma ray spectrometer measured the average surface abundances of the radioactive elements potassium (K, 1150 ± 220 ppm), thorium (Th, 220 ± 60 parts per billion), and uranium (U, 90 ± 20 parts per billion) in Mercury's northern hemisphere (Peplowski et al., 2011). The abundance of the moderately volatile element K, relative to Th and U, is inconsistent with physical models for the formation of Mercury requiring extreme heating of the planet or its precursor materials. Processes involving high temperatures such as vaporization of an early mantle and crust or a giant impact have been proposed to explain the large metal-to-silicate ratio of Mercury. Abundances of K, Th, and U indicate that internal heat production has declined substantially since Mercury's formation, consistent with widespread volcanism shortly after the end of late heavy bombardment 3.8 billion years ago and limited, isolated volcanic activity since (Peplowski et al., 2011).

Mercury's orbit about the Sun has a semimajor axis of 0.387 AU, an eccentricity of 0.206, and an inclination of 7° relative to the ecliptic. Therefore, the orbital distance from the Sun varies between 0.308 AU at perihelion and 0.466 AU at aphelion in the course of one revolution, causing significant tidal distortion of the planet (Burns, 1976; Van Hoolst and Jacobs, 2003). Furthermore, the near-surface layer of Mercury is exposed to a severe thermal environment in terms of elevated surface temperatures and high subsurface temperature gradients due to the planet's proximity to the Sun with an insolation of up to 15 kW m^{-2}. Related diurnal surface temperature variations between 90 and 740 K are greater than on any other planet or satellite in the solar system (Strom, 1987, 1997). Nevertheless, there are permanently shadowed regions at the bottoms of some craters at Mercury's poles where temperatures remain sufficiently low throughout a Mercurian year to insure the long-term stability of water ice (Paige et al., 2013).

Radar observations from the Earth have shown that the rotation period (58.6 days) is locked into a 3:2 resonance with the orbital period (87.7 days). As a consequence of the 3:2 spin–orbit coupling caused by tidal interactions with the Sun, one solar day on Mercury lasts 176 Earth days and corresponds to two revolutions or three rotations of the planet. While the distribution of solar irradiation is symmetrical between both hemispheres, the significant orbital eccentricity causes longitudinal variations superimposed on the latitudinal variation of the solar irradiation (Van Hemelrijck and Vercheval, 1981).

Owing to the lack of a substantial atmosphere, the surface of Mercury has been heavily cratered and fragmented by

impacts and small-particle bombardment resulting in a planet-wide, fine-grained, and thermally insulating regolith layer (Langevin, 1997). The thermal and electrical properties of the Mercurian regolith derived from Mariner 10 measurements are similar to those of the Moon (Chase et al., 1976). Even large-amplitude surface temperature perturbations are thus expected to rapidly fade away with depth and will be negligible below several thermal skin depths (Snyder Hale and Hapke, 2002; Vasavada et al., 1999).

10.02.7.2 Interior Structure

The large average density of $5430 \pm 10\ \mathrm{kg\ m^{-3}}$ (Anderson et al., 1987) is comparable to that of the Earth and Venus but much larger than that of the Moon and Mars. The corresponding zero-pressure density of about $5300\ \mathrm{kg\ m^{-3}}$ is even much higher than the uncompressed densities of Earth, Venus, and Mars, which are about 4100, 4000, and $3800\ \mathrm{kg\ m^{-3}}$, respectively. This suggests that Mercury contains a larger proportion of heavier elements such as iron than any other terrestrial planet, which is concentrated in a substantial core. The freezing of an inner pure iron core would be accompanied by the enrichment of light elements such as sulfur in a liquid outer core (**Figure 9**) and has implications for the concentration of mass toward the center. The mass concentration of iron should be about twice that in the Earth (Wasson, 1988).

Radio tracking of the MESSENGER spacecraft has allowed the determination of the low-degree and low-order spherical harmonic coefficients of Mercury's gravity field (Smith et al., 2012). Values of GM, $C_{2,0}$, and $C_{2,2}$ are, respectively, $22031.84\ \mathrm{km^3\ s^{-2}}$, -2.252×10^{-5}, and 1.253×10^{-5}. It is possible to infer Mercury's MoI from the gravitational and rotational parameters because of the planet's special spin state. Mercury is in a Cassini state wherein the axis of rotation, the orbit normal, and the normal to the Laplace plane remain coplanar as the spin vector and the orbit normal precess together about the latter with an ~300 000-year period (Margot et al., 2007).

As already mentioned, Earth-based radar observations also show that the amplitude of the 88-day forced libration in longitude is so large that the mantle and crust are librating independently of the core (Margot et al., 2007). This dynamic state together with the values of $C_{2,0}$ and $C_{2,2}$, the Earth-based radar measurements of the amplitude of Mercury's forced libration (35.8 ± 2 arcsec) and obliquity (2.06 ± 0.1 arcmin), and data on the precession rate and pole position provide the basis for calculating not only C/MR^2 but also C_m/C, where C_m is the axial MoI of Mercury's silicate shell. A model for Mercury's radial density distribution based on these results includes a solid silicate crust and a rocky mantle overlying an iron-rich liquid outer core (**Figure 10**). Mercury could have a solid inner core. The outer radius of the core is inferred to be 2030 ± 37 km (Margot et al., 2007; Smith et al., 2012). Mercury's core, with a radius about 83% of the planet's radius, contains most of the planet's iron.

Hauck et al. (2013) constructed models of the radial density structure of Mercury based on the radius and density of the planet and the moments of inertia of the planet and its silicate shell. These models are based on updated values of obliquity 2.04 ± 0.08 arcmin, the amplitude of the longitudinal libration 38.5 ± 1.6 arcsec, MoI $C/MR^2 = 0.346 \pm 0.014$, and $C_m/C = 0.431 \pm 0.025$ (Margot et al., 2012). Hauck et al. (2013) estimated that the top of the liquid core is at a radius of 2020 ± 30 km consistent with the location inferred by Smith et al. (2012). Hauck et al. (2013) found that the mean density above this boundary is $3380 \pm 200\ \mathrm{kg\ m^{-3}}$, and the density below the boundary is $6980 \pm 280\ \mathrm{kg\ m^{-3}}$. They infer the thickness of the outer solid shell to be 420 ± 30 km. They

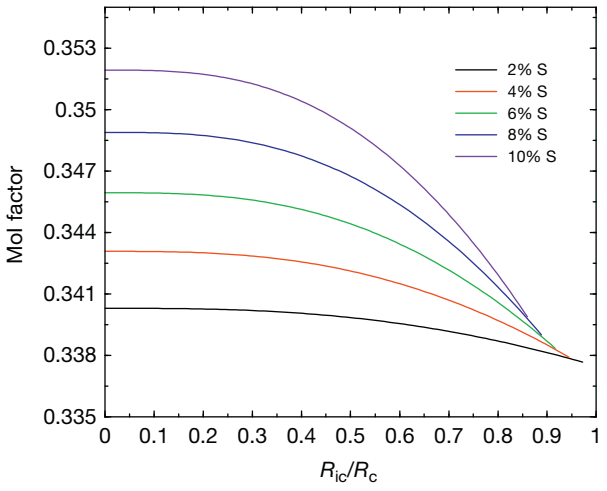

Figure 9 Mean moment of inertia (MoI) factor of a three-layer model of Mercury as a function of inner core radius R_{ic} and core chemistry. R_{ic} is given relative to the radius of the core R_c.

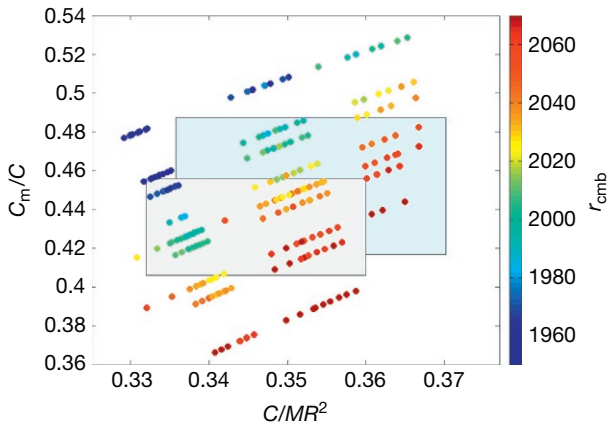

Figure 10 Model determinations of Mercury's core radius R_c (color-coded) as a function of the axial MoI factor, C/MR^2, and the ratio C_m/C between the axial MoI of the planet's solid portion and that of the entire planet. The latter depends on the coupling between core and mantle and provides clues to the physical state of the outermost part of Mercury's core. C_m/C would be around 0.5 for a liquid core or liquid outer core shell and about 1 in case of a solid core. Shaded boxes indicate the observational uncertainty range ($1-\sigma$) according to Smith et al. (2012) (turquoise) and Margot et al. (2012) (light gray). Reproduced from Steinke T (2012) *Modeling Mercury's Interior Structure and Tidal Deformation*. Bachelor's Thesis (in German), Karlsruhe Institute of Technology, Karlsruhe.

claim that these internal structure parameters are robust across a broad range of compositional models for the core and planet as a whole, a claim supported by their Monte Carlo internal structure modeling techniques.

There are several large gravity anomalies in Mercury's northern hemisphere with amplitude about 100 mGal. One of these anomalies coincides with the Caloris impact basin (Smith et al., 2012). The gravity field and the topography from MESSENGER's laser altimeter have been combined to produce a model of the crustal thickness of Mercury's northern hemisphere (Smith et al., 2012). The model assumes a crust–mantle density contrast of 200 kg m^{-3} and a mean crustal thickness of 50 km. The crust is generally thicker (50–80 km) near the equator and thins toward the north polar region (20–40 km); the regionally thinnest crust is located beneath the northern lowlands. The Caloris Basin overlies an area of locally thin crust, consistent with it being a mascon basin similar to those on the Moon.

Earth-based radar ranging data have suggested that the equatorial shape of Mercury has a significant ellipticity $(a–b)/a = (540 \pm 54) \times 10^{-6}$ and a center of figure CoF offset from the center of mass CoM of amplitude 640 ± 78 m in the approximate direction of the then unseen hemisphere (Anderson et al., 1996). MESSENGER laser altimeter measurements generally confirm these results, though there are some quantitative differences. The MESSENGER amplitude of the equatorial component of the CoF–CoM offset is 683 ± 146 m (Smith et al., 2010; Zuber et al., 2012) in approximately the same direction as the earlier radar ranging result. The equatorial shape of Mercury is not that of an equilibrium figure. The CoF–CoM offsets of all the terrestrial planets are plausibly attributed to hemispheric asymmetries in crustal thickness depending on the contrast $(\rho_m–\rho_s)/\rho_m$ between the densities of the mantle and the crust ρ_m and ρ_s, respectively. The magnitude of the CoF–CoM offset implies an excess crustal thickness of <12 km, which is comparable to that obtained for the Moon. Smith et al. (2010) inferred an even smaller crustal thickness difference. From a comparison between the equatorial shape and the gravitational equatorial ellipticity $C_{2,2}$ as inferred from the Mariner 10 flybys, Anderson et al. (1996) concluded that the Mercurian crust could be 200 ± 100 km thick if Mercury's equatorial ellipticity were entirely compensated by Airy isostasy (hydrostatic balance between crust and more dense mantle). Using the same approach, Smith et al. (2010) got a crustal thickness of 156 ± 23 km. They noted, however, that this is an overestimate since membrane stresses can contribute to the support of the equatorial ellipticity.

10.02.7.3 Composition

As discussed already in the preceding text, the major element surface composition of Mercury has been determined by the x-ray spectrometer on MESSENGER. The abundance of Fe in volcanic rocks at Mercury's surface is low. An upper bound on the average surface abundance of Fe of ~4 wt.% (Nittler et al., 2011) suggests that Mercury's silicate mantle is also low in iron. Most of Mercury's iron has segregated into its core. The low Fe abundance indicates that the surface *S* cannot be present primarily in the form of iron sulfides. More likely, the *S* occurs in Mg- and/or Ca-rich sulfides, which are stable under reducing conditions and present in highly reduced enstatite chondrite meteorites (Nittler et al., 2011). Relatively low surface abundances of Ti and Al (Nittler et al., 2011) suggest that Mercury's mantle contains limited amounts of high-density minerals as ilmenite and garnet.

It has been noted earlier that Mercury's relatively low Al/Si and Ca/Si ratios rule out the presence of a plagioclase-rich crust similar to that of the lunar highlands (Nittler et al., 2011). The Moon's ancient crust is believed to have formed by flotation of crystallized plagioclase-rich rocks that solidified from a global magma ocean. That such a crust never formed on Mercury is consistent with the low concentration of FeO in Mercury's mantle (Nittler et al., 2011). This does not rule out the possibility that Mercury had an early magma ocean. It only requires that upon solidification, the magma ocean, if it existed, did not form a plagioclase-rich, low-density crust.

If Mercury formed in a highly reducing environment as suggested by the low Fe and high S contents of its surface (McCubbin et al., 2012b; Nittler et al., 2011; Zolotov et al., 2013), then the planet's core might contain Si as well as sulfur (Malavergne et al., 2010). As already noted, Fe–S–Si alloys show liquid immiscibility at pressures <15 GPa and temperatures above the liquidus temperature (Morard and Katsura, 2010; Sanloup and Fei, 2004). Accordingly, FeS could have segregated and concentrated at the top of Mercury's core, perhaps forming a solid layer at the bottom of the silicate mantle (Hauck et al., 2013; Malavergne et al., 2010; Smith et al., 2012). In this case, the core–mantle boundary would not be a liquid–solid interface if the mantle is defined to be the silicate part of the planet.

However, the putative FeS layer is not a required feature of the acceptable density models of the planet. Using Bayesian inversion methods, Rivoldini and Van Hoolst (2013) calculated a broad range of compositionally distinct interior structure models of Mercury, assuming that sulfur is the only light element in the core. According to these models, Mercury has a core radius of 2004 ± 39 km, an average core density of 7233 ± 267 kg m^3, and a core sulfur content of 4.5 ± 1.8 wt. %. It is also concluded by these authors that the geodesy data impose strong constraints on the radius of the core and its composition in terms of average density or core sulfur content, whereas the mantle density is only weakly constrained by the geodesy data. Furthermore, Rivoldini and Van Hoolst (2013) pointed out that these models are not sufficiently diagnostic to distinguish between entirely liquid cores and the existence of a solid inner core.

10.02.7.4 Magnetic Field

Mercury is the only terrestrial planet other than Earth with an internally generated dipole-dominant magnetic field. The measured dipole moment is 190 nT R_M^3, where R_M is Mercury's mean radius (Anderson et al., 2011, 2012). The global planetary field is a southward-directed, spin-aligned, offset dipole centered on the spin axis. The offset is about 479 ± 6 km north of the geographic equator. The magnetic axis is tilted by $<0.8°$ from the rotation axis (Anderson et al., 2011, 2012). There is also evidence of crustal remanent magnetization on Mercury (Purucker et al., 2012). The northward offset of the dipole is equivalent to a strong quadrupole component described by the

Gauss coefficient $g_{2,0} = -74.6 \pm 4.0$ nT (Anderson et al., 2012). Mercury's magnetic field is unusual in the sense that multipolar components higher than degree 2 are small, while the dipole is dominant and the quadrupole is significant. Mercury's magnetic field is also weak compared with the Earth's field; Mercury's dipole moment is only about 10^{-3} that of the Earth's dipole moment.

There have been many attempts to explain the observed characteristics of Mercury's magnetic field. Thin-shell dynamos (Stanley et al., 2005; Takahashi and Matsushima, 2006); thick-shell dynamos (Heimpel et al., 2005); deep dynamos operating below a stably stratified, electrically conducting layer (Christensen, 2006; Christensen and Wicht, 2006; Manglik et al., 2010; Wicht et al., 2007); dynamos with induction feedback from magnetopause currents (Glassmeier et al., 2007a,b; Gómex-Pérez and Solomon, 2010; Gómex-Pérez and Wicht, 2010; Heyner et al., 2011a,b); and dynamos driven by precipitation of solid iron (Vilim et al., 2010) all can produce a weak field. However, thin-shell dynamos show a dipole offset much less than observed at Mercury or no quadrupole dominance over higher multipoles (Stanley et al., 2005). The feedback dynamo yields a planetary field that is axisymmetric but dominated by odd harmonics (Heyner et al., 2011b). Iron snow layers produce a field with a large octupole (degree 3) contribution and comparatively weak quadrupole structure (Vilim et al., 2010). Other dynamo models incorporate a sub-adiabatic heat flow at the core–mantle boundary to produce a stably stratified electrically conducting layer that filters out spherical harmonic terms of high degree and order that are the most variable in time. In these models, the field at the planetary surface is dominated by the axial dipole and quadrupole terms that are the most slowly time-varying components (Christensen, 2006; Christensen and Wicht, 2006; Stevenson, 1982; Wicht et al., 2007). In addition, zonal flows set up in the stably stratified layer preferentially reduce non-axisymmetric, low-degree terms (Christensen and Wicht, 2006), yielding a surface field that is weak, dipole-dominant with a substantial quadrupole component, and axisymmetric. The field structure produced by these models is highly dependent on the thickness of the stable layer and its dynamics (Manglik et al., 2010; Stanley and Mohammadi, 2008). It is not yet clear that we understand the processes behind the generation of Mercury's unusual magnetic field.

The presence of an internally generated magnetic field is consistent with an iron core that is at least partially liquid with an electrically conducting outer core of unknown thickness surrounding a solid inner core. Thermal evolution models indicate that the core would have solidified early in the history of Mercury unless a light alloying element such as sulfur was present. Even a small amount of sulfur is sufficient to depress the freezing point of a core alloy (Stevenson et al., 1983). The high surface abundance of sulfur suggests that despite its volatility and the closeness of Mercury to the Sun, sulfur is a likely constituent of the materials that formed Mercury and it therefore is present in Mercury's core. The enrichment of sulfur in the outer core upon freezing of an inner iron core would increase the depression of the freezing point and maintain a liquid outer core shell in spite of planet cooling (Figure 11). Thermal history models taking into account parameterized convective heat transport through the mantle indicate that bulk core sulfur concentrations of 1–5 wt.% are needed to retain a liquid outer core shell at the present time (Schubert et al., 1988; Spohn, 1991; Stevenson et al., 1983). Based on parameterized models of the coupled thermal, magmatic, and tectonic evolution of Mercury, Hauck et al. (2004) concluded that a dry-olivine mantle rheology, thorium-dominated radiogenic heating suggesting late silicate-mantle vaporization (Cameron et al., 1988), and a bulk core sulfur content of at least 6.5 wt.% are needed to explain both the planet's radial contraction of 1–2 km and the presence of a dynamo-driven, intrinsic magnetic field.

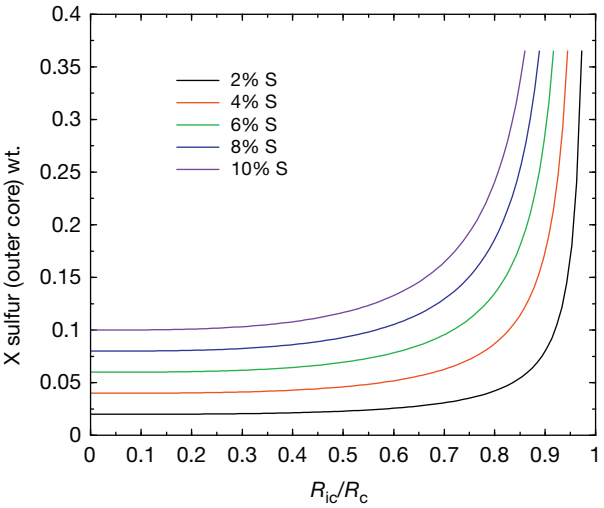

Figure 11 Sulfur content of the outer core of a three-layer model of Mercury as a function of inner core radius R_{ic} and core chemistry. R_{ic} is given relative to the radius of the core R_c.

Models of mantle convection including pressure- and temperature-dependent rheology demonstrate that the cooling history of a terrestrial planet is governed by the growth of its lithosphere, while the deep interior remains relatively hot. These models compare well to the parameterized convection calculations but produce thicker outer core shells at identical sulfur concentrations. Depending on the stiffness of the mantle rheology, a liquid outer core layer is then sustained even for sulfur concentrations as small as 0.2 wt.% consistent with cosmochemical arguments in favor of a volatile-poor planet (Spohn et al., 2001b). The 2 km radial contraction of Mercury in the absence of large-scale magmatism about 4 Gy may be linked to core shrinkage due to solid inner core growth and mantle cooling governed by lithospheric thickening and sluggish mantle convection (Schubert et al., 1988). If S and Si are present in Mercury's core, an FeS-rich layer could form at the top of the core and a part of it might be solid (Hauck et al., 2013; Smith et al., 2012). Such a layer could filter the dynamo-generated magnetic field as discussed earlier.

10.02.7.5 Future Exploration

Since Mercury is tidally flexed in its highly eccentric orbit about the Sun, the tidal Love numbers h_2 and k_2 can be derived from time-variable gravitational field measurements on a spacecraft orbiting the planet (Van Hoolst and Jacobs, 2003). The radial

displacement and tidal potential Love numbers h_2 and k_2, respectively, may provide useful constraints on the radial density and rigidity distribution and the extent of core differentiation for significant inner core sizes, that is, $R_i/R_c > 0.5$ (Steinke, 2012; **Figure 12**). Furthermore, the higher-order components of the gravitational field can be used to estimate crust thickness variations at short wavelengths and core–mantle boundary undulations at long wavelengths; the latter should be easily detectable due to the large size of Mercury's core relative to the planet's size (Spohn et al., 2001b).

No seismic data for Mercury exist. However, the periodic deformation of Mercury by solar tides may have important consequences for the planet's seismic environment. Owing to its highly elliptic orbit about the sun and its bound rotation, Mercury is exposed to strong tidal forces (Rivoldini et al., 2009; Van Hoolst and Jacobs, 2003). As a result, the seismic environment of Mercury may feature large numbers of lunar-like quakes.

10.02.8 Mars

The size of Mars is about half the size of the Earth and its mass is about 1/10 the mass of the Earth. The uncompressed density of roughly 3800 kg m^{-3} is significantly lower than the uncompressed densities of the Earth and Venus. The surface environmental conditions are the most Earthlike among the terrestrial planets with surface temperatures varying between 140 K at night in winter and 300 K at midday in summer. Mars is thought to be a one-plate planet, as are the Moon and Mercury, lacking plate tectonics at least at the present time.

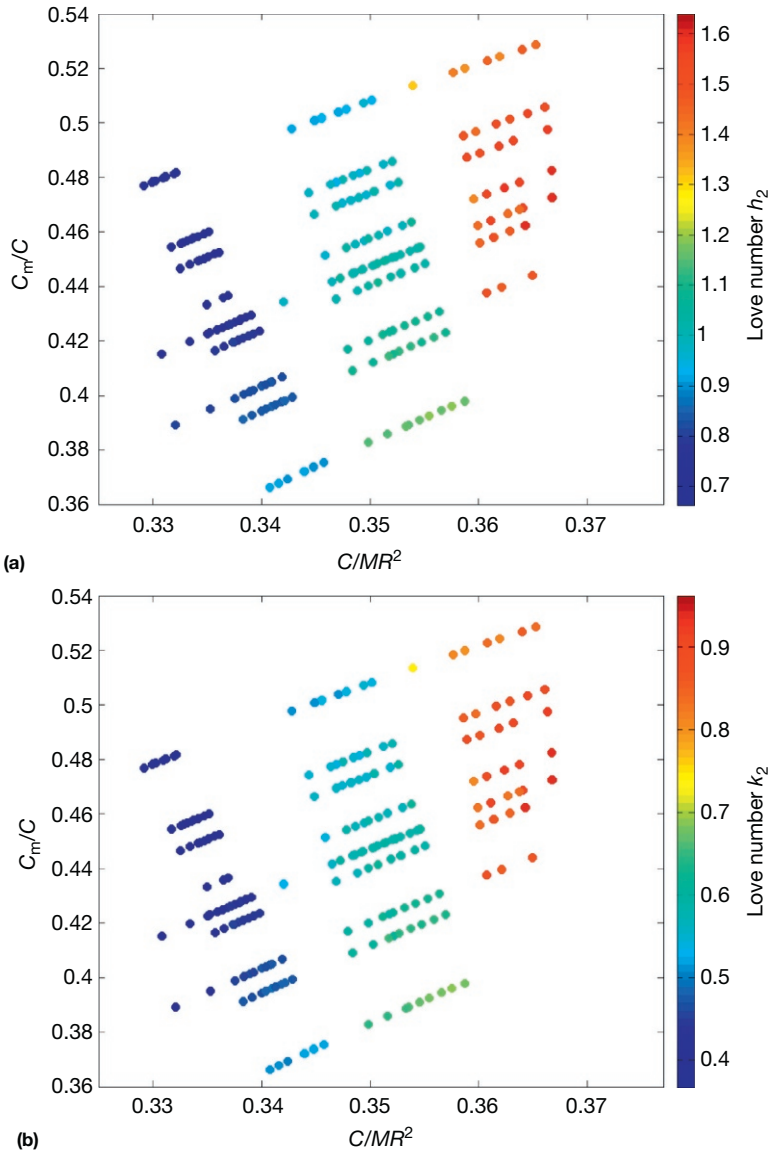

Figure 12 Model determinations of (a) radial displacement Love number h_2 and (b) tidal potential Love number k_2 of Mercury (color-coded) as a function of the axial MoI factor, C/MR^2, and the ratio C_m/C. Reproduced from Steinke T (2012) *Modeling Mercury's Interior Structure and Tidal Deformation*. Bachelor's Thesis (in German), Karlsruhe Institute of Technology, Karlsruhe.

10.02.8.1 General

The Martian surface is characterized by the hemispheric dichotomy between relatively sparsely cratered lowland plains in the north and the heavily cratered southern highland terrain once subjected to the postaccretional heavy bombardment of the inner solar system. The morphology of the boundary between the two hemispheres is dominated by outflow channels and chaotic terrain extending along broad gradual slopes rather than several kilometer high escarpments. Some portions of the dichotomy boundary are composed of fretted terrane and others are sculptured by scarps (Smith and Zuber, 1996). The Tharsis rise is situated close to the near-equatorial boundary between the northern and southern hemispheres and represents a giant volcanic dome established early in the planet's history. Major volcanoes such as Olympus Mons and the Tharsis Montes were emplaced on top of the Tharsis rise. The magmatic evolution of the planet is characterized by a progressive concentration of the volcanic activity to the Tharsis area and, to a lesser extent, to the Elysium area located about 100° to the west in the northern lowland plains. Baratoux et al. (2011) had analyzed Mars Odyssey gamma ray data of major volcanic provinces of Hesperian and Amazonian age and reported compositional trends that can be associated with variable degrees of partial melting of magmatic source regions in the upper Martian mantle. They have inferred a lithospheric growth rate of 17–25 km Gy^{-1} and a time rate of change of potential mantle temperature or secular cooling rate of 30–40 K Gy^{-1} that are in good agreement with estimates of elastic lithosphere thickness from gravity and topography data and numerical models of the thermal and chemical history of Mars, respectively (Baratoux et al., 2011; Grott et al., 2013).

For review articles on the geophysics and evolution of Mars, we refer the reader to Zharkov et al. (1991), Schubert et al. (1992), Zharkov and Gudkova (1997), Spohn et al. (1998, 2001a), Nimmo and Tanaka (2005), and Solomon et al. (2005). Grott et al. (2013) provided an extensive review of Martian igneous processes and their implications for the thermochemical evolution of major geochemical reservoirs (crust, mantle, and core) on Mars.

10.02.8.2 Interior Structure

The global topography and gravitational field of Mars have been determined with high accuracy using laser altimetry and two-way Doppler tracking of the MGS (Konopliv et al., 2006; Lemoine et al., 2001; Smith et al., 1999a,b; Zuber et al., 2000) and Mars Reconnaissance Orbiter (MRO) (Konopliv et al., 2011; Zuber et al., 2007). Doppler radio tracking data of a number of orbiting and landed spacecraft have provided basic information about the planet's mass ($GM = 42828.371901 \pm 0.000074$ km^3 s^{-2}, with G the gravitational constant (Lemoine et al., 2001)), spin-axis precession rate (-7606.1 ± 3.5 mass $year^{-1}$ (Kuchynka et al., 2014)), degree-2 tidal potential Love number k_2 (Konopliv et al., 2006, 2011; Marty et al., 2009; Yoder et al., 2003), and static and seasonal gravitational field. General improvements of the global gravity field solutions have been achieved by combining MGS and MRO tracking data with Mars Odyssey tracking data and surface tracking data from the Pathfinder and Viking 1 landers; the latter permits improvement of the parameters describing the orientation of the planet's rotational axis (Konopliv et al., 2006, 2011).

The rotational flattening of Mars results in a difference between the polar (north–south average) and equatorial radii of about 20 km (Seidelmann et al., 2002, 2005, 2007). The variation of topography with respect to the Martian geoid is about 30 km, representing the largest dynamic range of any terrestrial planet. The hemispheric dichotomy of Mars is related to an offset of about 3 km between the planet's center of mass and center of figure along the polar axis. The Tharsis bulge causes an additional offset of about 1.4 km along an equatorial axis in the direction of Tharsis. The topographic data show that the Tharsis rise consists of two broad rises, a larger, nearly circular southern rise superposed on the highlands that contains the Tharsis volcanoes and a smaller northern rise superposed on the lowlands that contains the shield volcano Alba Patera (Smith et al., 1999a).

Early attempts at modeling the deep interior structure of Mars suffered from poorly known values of its radius and MoI. Improved measurements of the planet's mass M, radius R, gravitational potential, and rotation rate by the Mariner, Viking, and Pathfinder spacecraft provided geodetic constraints required for models of the interior structure. The polar MoI of Mars has been derived from a combined analysis of low-degree gravitational field data and spin-axis precession estimates from MGS tracking and Mars Pathfinder and Viking Lander range and Doppler data. The reanalysis of the entire data set resulted in improved values of $C/MR_e^2 = 0.3650 \pm 0.0012$ (Yoder et al., 2003) and, with the collection of further spacecraft tracking and rotational data, $C/MR_e^2 = 0.3655 \pm 0.0008$ (Konopliv et al., 2006) and $C/MR_e^2 = 0.3644 \pm 0.0005$ (Konopliv et al., 2011), where R_e is Mars' equatorial radius fixed at 3396 km. These values are consistent with the previously accepted value of $C/MR^2 = 0.3662 \pm 0.0017$ (Folkner et al., 1997) that was referred to a mean planet radius R of 3390 km and thus corresponds to $C/MR_e^2 = 0.3649 \pm 0.0017$ if a correction factor $(R/R_e)^2$ is applied. Furthermore, the improved values of the MoI factor of Mars are consistent with the model of a mostly hydrostatic planet with a nonhydrostatic contribution to the MoI factor entirely related to the axisymmetric distribution of topographic loads about Tharsis (Kaula, 1979; Reasenberg, 1977).

Using the improved values of the MoI factor of Mars and taking into account the planet's gravitational oblateness and minor contributions due to the Tharsis rise suggest a stronger concentration of mass toward the center than previously thought, with consequences for the planet's bulk chemistry and interior structure (Konopliv et al., 2011; Sohl et al., 2005; Zharkov and Gudkova, 2005; Zharkov et al., 2009). As a consequence of the improved lower MoI factor, the Martian mantle may be less dense, about several tens of kg m^{-3}, with a smaller iron content than previously thought if crust thickness and core size are specified. It further implies that the Martian crust is several tens of kilometers thicker than previously thought if crust and mantle densities and core size are given. Finally, it suggests several tens of kilometers larger core radii if other parameters like core density, crust density, and crust thickness are fixed (**Figure 13**). If the crust thickness increases, dense mantle material will be replaced by less dense crust material, thereby reducing the planet's MoI factor. The mass deficit that

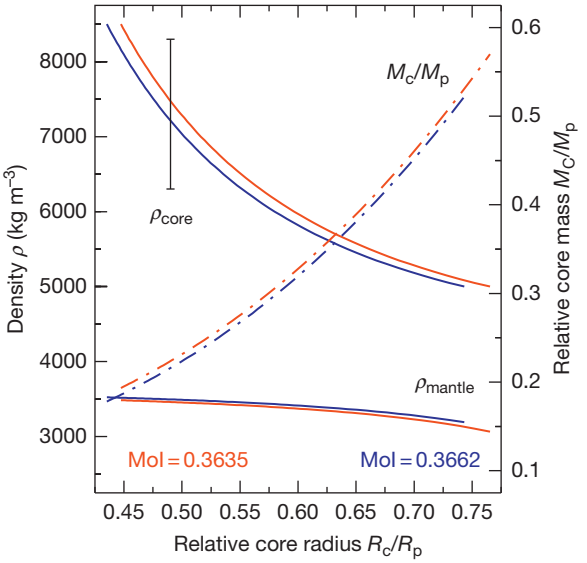

Figure 13 Two-layer model determinations of mantle and core density and core mass fraction M_c/M_p of Mars versus relative core radius R_c/R_p based on an MoI factor of 0.3635 (red) and 0.3662 (blue), respectively. Martian core densities are thought to range between those of γ-iron and iron sulfide as indicated by the error bar. Figure 14 Contours of mantle density ρ_m as a function of relative core radius R_c/R_p and crust thickness based on an MoI factor of 0.3635 (red) and 0.3662 (blue), respectively. Mean crustal density is fixed at (top) 2700 and (bottom) 3100 kg m^{-3}. Adapted from Sohl F, Schubert G, and Spohn T (2005) Geophysical constraints on the composition and structure of the Martian interior. *Journal of Geophysical Research* 110: E12008, http://dx.doi.org/10.1029/2005JE002520, with permission American Geophysical Union; Copyright 2005.

arises cannot be compensated simply by increasing the core density, however, since this would even further reduce the MoI factor for a given core size. Therefore, to account for both the planet's mean density and the mean MoI factor at constant core size, the mantle density will be required to increase and core density simultaneously to decrease. In terms of composition, the presence of a thicker crust requires the silicate mantle to be more enriched in iron with an increasing amount of light alloying elements such as sulfur concentrated in the core. Additionally, the contribution of a thicker crust to the planet's bulk composition will become more pronounced (**Figure 14**). However, one should be cautious against changes in the mantle iron concentration that would affect the MoI factor by shifting the locations of pressure-induced mineral phase transitions to other depths (Mocquet et al., 1996, 2011).

Together with the planet's mean density and axial MoI, the solar tidal potential Love number k_2 imposes additional constraints on the size and physical state of the Martian core (Rivoldini et al., 2011; Sohl et al., 2005; Verhoeven et al., 2005; Zharkov and Gudkova, 2005; Zharkov et al., 2009). The determination of $k_2 = 0.153 \pm 0.017$, based on the analysis of 3 years of MGS radio tracking data (Yoder et al., 2003), or $k_2 = 0.152 \pm 0.009$, if combined with additional years of Odyssey tracking data (Konopliv et al., 2006), indicates that the planet's interior is still sufficiently hot that at least the outer part of the Martian core is liquid. Based on a joint analysis of the longest available data set of both missions, Marty et al. (2009) reported values $0.11 < k_2 < 0.13$ for different data subsets. Their preferred solution $k_2 = 0.120 \pm 0.003$ is still consistent with the existence of a dense lower silicate mantle surrounding a liquid metallic core. A larger value $k_2 = 0.164 \pm 0.009$ results from 2 years of MRO radio tracking data, augmented by additional MGS and Mars Odyssey tracking and after correction of the atmospheric tide (Konopliv et al., 2011). The determination of k_2 based on gravitational field observations is largely dependent on data selection and bias effects. This could be a plausible reason for the notable difference between the k_2 estimates by Yoder et al. (2003) and Konopliv et al. (2006, 2011) as compared to that of Marty et al. (2009).

The tidal forcing of Mars allows inference of the planet's bulk rheological properties from the satellites' orbital evolution that is closely connected to the dissipation of tidal energy within the Martian interior (Burns, 1992). Former estimates of Mars' tidal quality factor cover a broad range of $Q = 100 \pm 50$ (Smith and Born, 1976; Yoder, 1982). A small apparent tidal lag angle γ of about 0.7° has been obtained from a combined analysis of Viking and MGS observations of Phobos' orbital position (Bills et al., 2005). The corresponding estimate of

Mars' tidal quality factor is $Q = 1/\tan\gamma \approx 85$. Using orbital position observations of Phobos and Deimos from 1877 to 2005, including MGS and Mars Express observation, Lainey et al. (2007) found $Q = 79.91 \pm 0.69$, provided that $k_2 = 0.152$ and $GM_{Ph} = 0.68 \times 10^6$ m^3 s^{-2} are assumed for Mars' tidal Love number and Phobos' mass, respectively. Zharkov and Gudkova (1997) concluded that the tidal phase lag is not sensitive to the Martian crust and upper mantle, but the dissipation mainly occurs at greater depth in the middle mantle and lower mantle. A small correction on the order of 3 $k_2/Q \sim 0.005$ arises from anelastic softening due to transient or time-dependent creep in the tidal frequency domain. Zharkov and Gudkova (2005) discussed seismic velocity dispersion due to anelasticity. Therefore, the resultant value of the seismic Love number $k_2 = 0.159 \pm 0.009$ should be used as observational constraint on structural models of the Martian interior in addition to the planet's MoI factor. The most recent determinations of k_2 and C/MR_e^2 (Konopliv et al., 2011) are in good agreement with a Martian core radius ranging between 1700 and 1800 km (Konopliv et al., 2006, 2011; Rivoldini et al., 2011; Zharkov et al., 2009).

The first observational estimate of the duration of the Chandler wobble of Mars, a free long-period oscillation of the entire planet, was obtained by Konopliv et al. (2006). In many publications, in which models of the interior structure of Mars were constructed, the predicted model values of the Chandler period were about 200 days. In the observational data, the Chandler term at a period of 210 days is a combination of the free wobble and 1/3 of the annual (229 days) forced wobble that may cause the free wobble signal to shift to longer periods (see **Chapter 10.04** in this volume). Accounting for inelasticity of the planet's interior owing to transient or time-dependent creep, Zharkov and Gudkova (2009) calculated the Chandler wobble period for a set of Martian interior structure models that satisfy the mean MoI factor of $I/MR^2 = 0.3655 \pm 0.0008$ (Konopliv et al., 2006) and corresponding elastic Love numbers $k_2 = 0.145 \pm 0.017$ (Yoder et al., 2003) and $k_2 = 0.148 \pm 0.009$ (Konopliv et al., 2006), respectively. Whereas the minimum Chandler period is $202.8 < T_w < 203.4$ days, its shift to longer periods due to inelasticity δT_w is in the range $0.981 < \delta T_w < 1.42$ days. Combining both estimates, the Chandler wobble period of Mars is found to be in the interval $203.8 < T_w + \delta T_w < 204.8$ days (Zharkov and Gudkova, 2009).

Whereas the gravitational field of the elevated southern hemisphere is relatively featureless and implies a state of near-isostatic compensation, the northern lowland plains reveal a wider range of gravitational anomalies (Smith et al., 1999b). The dichotomy boundary is not clearly resolved on the gravity map, whereas the Tharsis Montes, Olympus Mons, Valles Marineris, and Isidis impact basins are visible as individual gravitational anomalies in the areoid. Major gravity highs are associated with the Tharsis and Elysium volcanoes indicating that they are not isostatically compensated. Large impact basins reveal negative annular anomalies with a central positive anomaly. The global crust and upper mantle structure of Mars has been derived from MGS measurements of gravity and topography. The Bouguer gravity has been interpreted in terms of crustal thickness variations. In these models, the thickness of the southern hemisphere crust decreases progressively from south to north, whereas the northern lowlands are characterized by a more uniform crust thickness (Neumann et al., 2004; Zuber et al., 2000). Elastic thickness models based on gravity and topography data can be used to infer additional information about the planet's rheological structure with important implications for the thermal and volatile evolution of the Martian interior (Guest and Smrekar, 2007; Jakosky and Phillips, 2001).

Plausible Martian crust densities range from 2700 to 3100 kg m^{-3} based on end-member-type compositional models of the Martian crust (Babeyko and Zharkov, 2000; Wieczorek and Zuber, 2004). The lower estimate of about 2700 kg m^{-3} represents an andesitic–basaltic composition obtained from Pathfinder-APXS measurements of soil-free Martian rocks (Brückner et al., 2003). The upper estimate of about 3100 kg m^{-3} (Pauer and Breuer, 2008) represents porous basaltic shergottites (Britt and Consolmagno, 2003) believed to be samples of the Martian crust released during one or several giant impacts (McSween, 1994). These rocks are further believed to represent end-members of the composition of well-mixed Martian soil on a planetary scale (Nimmo and Tanaka, 2005). Using a spectral localization method to analyze volcanic surface loads, Belleguic et al. (2005) had reported considerably higher crustal densities beneath the Elysium rise of 3270 ± 150 kg m^{-3}, whereas the load densities related to the major Martian volcanoes except Alba Patera are best constrained by a value of 3200 ± 100 kg m^{-3}. The latter density is similar to that of Shergotty-type basaltic meteorites thought to have originated from Mars. This implies that the Martian lowland crust is composed of more mafic constituents than the southern highland crust and that the hemispheric difference in elevation may be mainly attributed to a Pratt-like isostatic compensation mechanism (Belleguic et al., 2005). Load densities of ~3350 kg m^{-3} have been obtained for the Tyrrhenus Mons highland volcano provided that low-density pyroclastic deposits make up to 30% of the load volume (Grott and Wieczorek, 2012), suggesting that basaltic lava flows on Mars are compositionally similar and comparable to Martian meteorites. This is supported by high-resolution radio science tracking data of the Tharsis province acquired by the Mars Express (MaRS experiment) and MRO spacecraft. Whereas the major volcanic shields of the Tharsis province, except Ascraeus Mons, were inferred to be mainly composed of high-density lava, the gravitational signature of Olympus Mons could be in agreement with bottom loading in terms of a buoyant mantle plume (Beuthe et al., 2012).

Present estimates of the mean crustal thickness of Mars are entirely based on indirect geophysical studies like local relationships between gravity and topography and/or geochemical arguments and may range between 30 and 80 km (Neumann et al., 2004; Solomon et al., 2005; Wieczorek and Zuber, 2004), although crust thicknesses of up to about 100 km are consistent with global geophysical constraints (Gudkova and Zharkov, 2004; Kavner et al., 2001; Sohl and Spohn, 1997; Sohl et al., 2005). Assuming a Bouguer reduction density of 2900 kg m^{-3} and a crust–mantle density contrast of 600 kg m^{-3}, crust thicknesses vary from about 6 to 102 km, the former of which is located beneath the center of Isidis and the northwestern floor of Hellas Planitia (Neumann et al., 2004). Larger crust thicknesses might be unlikely, however, since ductile flow in the warm lower crust could cause

relaxation of lateral crustal thickness variations (Nimmo and Stevenson, 2001; Zuber, 2001; Zuber et al., 2000). The crust thickness could be further limited by the pressure-induced transition from basalt to eclogite that may occur in the lower Martian crust (Babeyko and Zharkov, 2000). Using the technique of petrophysical modeling (Sobolev and Babeyko, 1994) to construct mineralogical, density, and seismic velocity profiles of the deep Martian crust, Babeyko and Zharkov (2000) first derived the equilibrium mineralogical composition by numerical thermodynamic simulation for a given bulk chemical composition and local P–T conditions, whereas the local density and seismic velocities were calculated in a second step from the mineralogy. Here, it is assumed that the bulk chemical composition of the crust is represented on average by four basaltic Martian meteorite classes (Shergotty, Zagami, EETA 79001, and lithologies A and B).

Vector magnetic field observations, obtained at altitudes between about 100 and 200 km subsequent to orbit insertion of the MGS spacecraft, have been compiled into a global magnetic field map of the Martian crust (Connerney et al., 2005). Although Mars lacks an intrinsic magnetic field at present, the Martian crust acquired intense magnetization in the past, hinting at the existence of a strong internally generated field at that time. Crustal remanent magnetization has been found to exceed that of Earth by more than an order of magnitude and is mainly confined to the most ancient, heavily cratered southern highland terrain (Acuña et al., 1999; Connerney et al., 1999; Quesnel et al., 2007). The bottom of the magnetized layer is constrained by the Curie temperature of its magnetic carriers, whereas the top of the layer is given by the thickness of the uppermost crust that has been demagnetized by impact events. Magnetized source bodies are believed to be situated at depths of less than ~100–90, 90–80, or 55–45 km, provided hematite, magnetite, and pyrrhotite are the magnetic carrier minerals that predominate within the Martian crust (Arkani-Hamed, 2005). Early serpentinization or chemical water–rock reaction at elevated pressure of the Martian crust in the Noachian has been suggested to form enough magnetic carrier minerals such as magnetite (Quesnel et al., 2007). If serpentinization and related crustal density reduction were limited to the southern hemisphere, however, this model could explain not only the apparent concentration of strong magnetic anomalies in the southern highland terrain but also the hemispheric dichotomy of Mars in terms of topography variation and merely subdued gravity changes across the dichotomy boundary (Quesnel et al., 2007, 2009). Early formation of the crustal dichotomy could have resulted in a single-hemisphere dynamo with strong magnetic fields and strongly magnetized crustal units in the southern hemisphere (Stanley et al., 2008).

Linear magnetic features of up to ~2000 km in length are frequently oriented in the east–west direction, some resembling a pattern of band-like features of alternating magnetic polarity (Connerney et al., 2001). The Martian crust may have been magnetized during a time span of only a few hundred million years after planet formation when an active core dynamo driven by thermal convection produced an intense global magnetic field. If crust magnetization occurred later in the planet's evolution, a core dynamo driven by chemical convection associated with inner core growth would be more likely (Connerney et al., 2004). The lack of crustal magnetization in the vicinity of large impact basins (Hellas, Argyre, and Isidis) is commonly attributed to cessation of the core dynamo when these basins formed about 4 Gy during the Noachian period and demagnetized underlying crust layers (Acuña et al., 1999). Alternatively, however, impact basin formation may predate the onset of the Martian core dynamo so that the magnetization of the southern highland terrain was caused by localized heating events followed by rapid cooling below the Curie temperature (Schubert et al., 2000). The timing of the Martian dynamo remains a subject of debate. By analyzing magnetic anomalies in the regions surrounding Tyrrhenus Mons and Syrtis Major, two volcanoes that were active during the late Noachian and Hesperian, Milbury et al. (2012) concluded that the Martian dynamo was active into the Hesperian, perhaps as late as 3.6 Gy. However, Lillis et al. (2013) studied the magnetic anomalies of large Martian craters and claimed that the Martian dynamo ceased operating before the Hellas and Utopia impacts, between 4.0 and 4.1 Gy. The almost complete demagnetization of the Tharsis rise and other volcanic features implies that thermoremanent magnetization on Mars is confined to a relatively thin layer less than a few tens of kilometers thick. In a similar way, a possible former magnetization of the northern lowland crust may have been entirely erased by catastrophic volcanic flooding during the Hesperian period (Head et al., 2002). Connerney et al. (2005) argued that variations in the crustal magnetic field can be associated with major geologic and topographic features, sometimes reminiscent of transform faults in oceanic crust on Earth. It is speculated that arcuate and linear magnetic features, similar to but much larger than those observed near mid-ocean ridges on Earth, could imply that early Noachian crust formation on Mars was accompanied by plate tectonics associated with crustal spreading in the presence of a reversing dynamo (Connerney et al., 2005).

10.02.8.3 Composition

Anders et al. (1971) were among the first who discussed terrestrial planet formation in the presence of planetesimals with different oxidation degrees. This idea was further developed by Ringwood (1977, 1979) and considered in more detail by Wänke (1981, 1991), Dreibus and Wänke (1985, 1989), and Wänke and Dreibus (1994). It appears correct to say that the Dreibus–Wänke (DW) model is as important for Mars as Ringwood's pyrolite model for understanding Earth's interior (Ringwood, 1975).

The DW model is based on considerations of element correlations in SNC meteorites (named after Shergotty, Nakhla, Chassigny, almost certainly representing distinct classes of Martian meteorites) and cosmochemical constraints, suggesting that Mars was formed by the homogeneous accretion of two geochemically distinct components, a highly reduced refractory component and a volatile-rich oxidized one. In this model, the former did not include elements more volatile than sodium or potassium; however, it contained all other elements in the same abundance ratios as in CI chondritic material. The water content of that component was taken to be ~7.3 wt.% (Dreibus and Wänke, 1989). Later, this estimate was increased up to 18–22 wt.% (see also Volume 1 of *Treatise on Geochemistry*). This suggests that the planet captured a substantial amount of water during its formation. Iron and all siderophile

elements are in the metallic state, and even silicon is partly metallic. This material existed mainly in the feeding zone of the growing Earth (Dreibus and Wänke, 1989; Wänke and Dreibus, 1988). In this model, Mars is differentiated into a FeO-rich silicate mantle containing radiogenic heat sources in terrestrial abundances and a sulfur-rich Fe–Ni–FeS core of about 22% of the planet's mass containing about 14 wt.% sulfur with a radius roughly 50% of the surface radius. Following the successful determination of the planet's axial MoI from Mars Pathfinder tracking observations (Folkner et al., 1997), one immediate question was whether the cosmochemical DW model (Dreibus and Wänke, 1985) is consistent with structural models of the Martian interior that satisfy the most recent data on the MoI of Mars (Bertka and Fei, 1997, 1998a; Kavner et al., 2001; Sohl and Spohn, 1997; Yoder and Standish, 1997; Zharkov, 1996; Zharkov and Gudkova, 2000).

Longhi et al. (1992) recasted the mantle composition of Dreibus and Wänke (1985) into a pressure-dependent mineralogy resulting in an upper olivine-rich part, a transition zone composed of silicate spinel, and a lower perovskite-rich layer. The model provides a mean dimensionless MoI factor of 0.353 and is consistent with the geochemical constraint of a bulk Fe/Si ratio of 1.71 representative of the composition of CI carbonaceous chondrites. From models that use identical sets of material parameter values for crust, mantle, and core, as derived from geochemical analyses of SNC meteorites and laboratory studies, and that take into account self-compression and thermal expansion of the Martian interior, a number of authors concluded that it is difficult to reconcile the assumption of a bulk planet CI Fe/Si ratio with the observed value of the axial MoI factor (Bertka and Fei, 1997, 1998a; Sohl and Spohn, 1997; Yoder and Standish, 1997). In contrast, Zharkov and Gudkova (2000) suggested that the observational data basis is not sufficient to assess the validity of the cosmochemical DW model and hence the correctness of the chondritic hypothesis. At present, interior structure models can be constructed that either satisfy or disprove the chondritic hypothesis. Rivoldini et al. (2011) further concluded that geodesy data are not diagnostic of the bulk planet Fe/Si ratio and the mineralogy of the mantle and the crust, even if the thermal state of the Martian mantle is specified.

The geochemical estimate of mantle differentiation and the volatile evolution of Mars are uncertain owing to inherent complexity (Guest and Smrekar, 2007; Jagoutz, 1991), and the formation age and average thickness of the crust are still not well constrained and may vary by a factor of 2 (Wieczorek and Zuber, 2004). Analysis of the SNC meteorites, estimates of the elastic lithosphere thickness, and the dissipation of tidal energy suggest that a few tens of ppm of water are still present in the Martian mantle (Grott et al., 2013). Estimates of the planet's initial bulk water content range from a few ppm (Wänke, 1994) to rheologically significant amounts of ~200 ppm (McCubbin et al., 2010a, 2012a; McSween et al., 2001) for wet mantle conditions, which could result in a melting point reduction of ~100 K (Katz et al., 2003) relative to a dry mantle. If the mantle was wet, magmatic degassing could have supplied a substantial amount of water to the Martian surface early in its history. Using age determinations of zircons and incompatible element abundances of impact melt rocks in a putative ancient southern highland regolith breccia, Humayun et al. (2013) concluded that the magmatic differentiation of the Martian highland crust occurred within the first 100 My after planet formation, a timescale comparable to Earth's and the Moon's, thereby resulting in an average crustal thickness of ~50 km. This suggests to the authors that an equally rapid release of volatiles from the interior is likely and has had important implications for early Martian climate and habitability (Jakosky and Phillips, 2001; Marty and Marti, 2002). It remains unresolved, however, whether the water contents derived from analysis of Shergottites, the most abundant Martian meteorites, correspond to the ancient or present mantle since the formation age of the Shergotty meteorites and the role of magmatic degassing of their source region are still debated (Balta and Mcsween, 2013; Grott et al., 2013).

The Martian core is sufficiently large that even small changes in core size will result in significant changes of core volume. Since the core contributes most of the iron, a significant change in core volume can be expected to result in a notable modification of the bulk planet Fe/Si ratio. Modifications of the Fe/Si ratio due to changes in core volume may be partly compensated, however, by variable mantle iron contents in combination with crust thickness variations because of the significant mass fraction of the planet's silicate portion. The bulk planet Fe/Si ratio is also notably dependent on the thermal state of the core because of the temperature dependence of the equation-of-state parameters of iron and iron sulfide as the main core constituents (Buono and Walker, 2011; Chudinovskikh and Boehler, 2007; Fei et al., 1995; Kavner et al., 2001).

In **Figure 15**, radially symmetrical density models of the Martian interior are compared for variable sulfur contents of

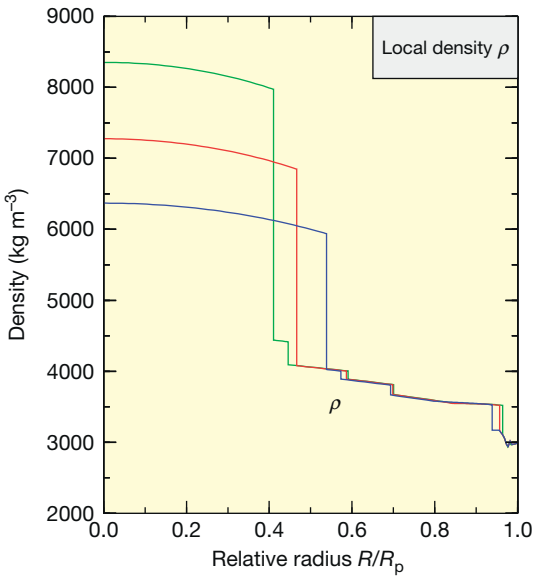

Figure 15 Radial density distribution of the Martian interior as a function of relative core radius R_c/R_p and core composition using the low-temperature crust model of Babeyko and Zharkov (2000). If the core were composed of pure iron (green), it would be small enough to enable the pressure-induced phase transformation from spinel to perovskite. In turn, a pure iron sulfide core (blue) would be too large and mantle pressures therefore too low for the phase transition to occur. The intermediate density profile (red) refers to a Fe–FeS core containing iron and iron sulfide in equal amounts.

the core. The sulfur content of the Martian core is unknown, but geochemical models predict a sulfur-rich core (McSween, 1994). Multianvil-press experiments to examine the effects of both nickel and sulfur on the partitioning of oxygen between liquid Fe metal and ferropericlase suggest that the oxygen content of a more sulfur-rich core could be in the range 2–4 wt.% if it is in equilibrium with the FeO-rich Martian mantle (Tsuno et al., 2011). Furthermore, light constituents such as iron hydride may also be present in the core depending on the amount of hydrogen dissolved in the core alloy when subject to the pressure and temperature conditions possibly prevailing in the Martian core (Gudkova and Zharkov, 2004; Zharkov, 1996; Zharkov and Gudkova, 2000). The way how hydrogen could enter the Martian core is discussed in more detail by Zharkov and Gudkova (2005). If core size and density are specified, more iron-rich alloys can be accommodated with increasing hydrogen content and/or core temperature, thereby increasing the planet's bulk Fe/Si ratio.

10.02.8.4 Mineralogy

Bertka and Fei (1997) obtained the sequence of mineralogical phase assemblages stable in the Martian mantle at elevated temperatures and up to core–mantle boundary pressures from high-pressure and high-temperature experiments using synthetic mineral mixtures according to the mantle composition of Dreibus and Wänke (1985). In **Figure 16**, it is seen that the upper part of the mantle then contains olivine, clinopyroxene, and garnet, whereas orthopyroxene is only present at pressures below 9 GPa. In the mantle transition zone at pressures above 13.5 GPa, β-spinel (wadsleyite) and clinopyroxene are subsequently replaced by γ-spinel (ringwoodite) and majorite until completion at about 17 GPa. A hot lower mantle is found to contain Mg–Fe silicate perovskite, magnesiowüstite, and majorite in the absence of $CaSiO_3$ perovskite (Bertka and Fei, 1997).

Verhoeven et al. (2005) established empirical relationships between the most abundant mantle minerals based on a compilation of chemical compositions and related mineral assemblages of the silicate mantles of Mars and Earth. A perovskite layer at the base of the Martian mantle could only exist if pressures and temperatures in the mantle are sufficiently high for the occurrence of the mineral phase transitions. Therefore, the possible existence of a perovskite lower mantle and its stable phase assemblage in Mars not only depends on the core–mantle boundary pressure, that is, the size and composition of the core, but also is sensitive to the temperature distribution deep inside the planet.

The stability range of such a putative perovskite lower mantle and its consequences for mantle plume dynamics were studied by van Thienen et al. (2006), comparing the model mantle mineralogy from Bertka and Fei (1997) to the model EH45 from Sanloup et al. (1999). Furthermore, uncertainties of a few 100 K in the experimental determinations of the pressure–temperature relation of the perovskite phase transformation and poor knowledge of the planet's thermal state (Breuer and Spohn, 2003) are taken into account. For a nominal core sulfur content of 14 wt.%, van Thienen et al. (2006) found that a perovskite layer sufficiently thick to affect mantle dynamics can be kept for both hot and cold end-member-type mantle temperature profiles (Breuer and Spohn, 2003). Thus,

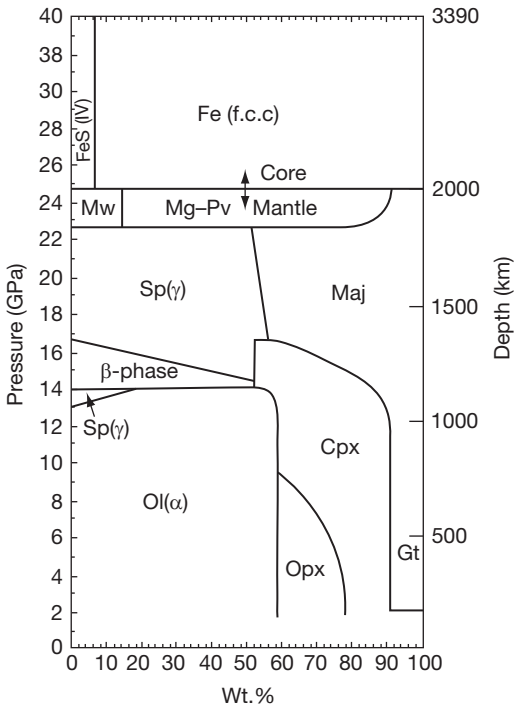

Figure 16 Mineral phase assemblages (in wt.%) of the Martian mantle as a function of pressure based on the chemical compositional model of Dreibus and Wänke (1985). Abbreviations are Ol, olivine; Opx, orthopyroxene; Gt, garnet; Maj, majorite; Sp, spinel; Mw, magnesiowüstite; and Mg–Pv, Mg–Fe silicate perovskite. The location of the core–mantle boundary is from Fei et al. (1995). Adapted from Bertka CM and Fei Y (1997) Mineralogy of the Martian interior up to core–mantle boundary pressures. *Journal Geophysical Research* 102: 5251–5264, with permission American Geophysical Union; Copyright 1997.

it is feasible that at least in the early evolution of the planet, when mantle temperatures were much higher, a thin perovskite layer hovered above the core–mantle boundary. Alternatively, a smaller size of the Martian core in favor of a deep perovskite layer is conceivable if a solid inner core composed of γ-iron would be present and surrounded by a less dense, volatile-rich liquid outer core. Given the present uncertainty on the location of the transition to the perovskite phase, the possible existence of a thin perovskite layer in the lower mantle cannot be excluded even in the presence of a large, fully molten core as suggested by the geodetic data (Rivoldini et al., 2011). A definite answer to this problem has to await the successful deployment and operations of a passive seismological experiment at the Martian surface using broadband seismometers (Gudkova et al., 2014).

If the geochemical requirement of a CI chondrite bulk composition is kept, the mantle density profile obtained from the experimentally determined sequence of mineralogical phase assemblages (Bertka and Fei, 1997) and a core density consistent with a core sulfur content of 14 wt.% would result in a mean MoI factor of 0.354 (Bertka and Fei, 1998a). However, this model that lacks a perovskite layer at the base of the mantle would require a crust thickness of 180–320 km assuming a crustal density of 2700–3000 kg m^{-3}. Since such a crust thickness is considered to be unrealistically large, a CI

chondrite bulk composition of the Martian interior as assumed by Dreibus and Wänke (1985) may be questionable (Bertka and Fei, 1998b). Models using the same mantle density profile and a range of model core compositions but allowing for the MoI factor of 0.3662 as obtained from the Pathfinder measurements generally produce bulk Fe/Si ratios below the CI chondrite value of 1.71. This may suggest that the formation of Mars and the terrestrial planets cannot be explained solely by the accretion of CI carbonaceous chondrite material (Bertka and Fei, 1998b). Using Bayesian inversion methods, Rivoldini et al. (2011) estimated median and probability intervals of geophysical and geochemical key parameters for compositionally distinct interior structure models of Mars. According to these models, the radius of the Martian core is 1794 ± 65 km or ~53% of the planet's radius with a core sulfur content of 16 ± 2 wt.%. As a consequence, these authors claimed that, by adjusting equation-of-state parameters, models of the Martian interior can be constructed, which are in agreement with the mantle composition of Dreibus and Wänke (1985), a core sulfur content of 14 wt.%, a bulk Fe/Si ratio of 1.71, recent determinations of the planet's axial MoI and tidal Love number, and most recent estimates of crust density and thickness.

10.02.8.5 Martian Seismicity

A three-axis short-period seismometer on board the Viking Lander 2 at Utopia Planitia collected more than 600 h of data to explore the seismic environment of Mars (Anderson et al., 1976, 1977). The seismometer was added late in the mission planning and therefore had to be installed on the top of the lander structure. Hence, wind noise contaminated the seismic data. No large seismic events were detected, indicating that Mars is less seismically active than Earth by an estimated three orders of magnitude. A seismic signal from one small quake was possibly recorded. Its tentative analysis suggested that it had a magnitude of 3 and had occurred at a distance of 110 km. Identification of late arrivals implied the presence of a crust with a thickness of 15 km near the landing site. However, it cannot be ruled out that wind gusts mimicked a seismic event.

While the seismicity of Mars is largely unexplored, there are indications that Mars could be quite active. Most morphological features on Mars seem to be only partially isostatically compensated (Zuber et al., 2000). These include the Tharsis rise as well as the Chryse and Amazonis basins. Regions of partial isostatic compensation on Earth are generally the most seismically active. Tectonic stresses implied by a lack of compensation are known to be in the 10 to 100 bar range and stress drops in earthquakes are in the same range. Hence, Mars could be tectonically active, though seismicity may be more localized in the vicinity of preexisting faults. Andrews-Hanna et al. (2008) explained the contractional strain history of Mars as inferred from the ages and locations of Noachian to Early Hesperian strike-slip faults southwest of Tharsis by the interaction of plume-induced contraction during Tharsis formation in the Noachian with uniform contraction due to secular cooling of the entire planet. The best-preserved fault in their mapped set of strike-slip faults has a length of ~200 km and with measured lateral offsets ranging from 5 to 9 km.

The early tectonic evolution of Mars in terms of Tharsis-induced loading stresses superimposed on a uniform contractional stress is thought to be accommodated by quite a number of compressional and extensional surface features such as wrinkle ridges and graben. Based on a global compilation of compressional and extensional faults derived from Mars Orbiter Laser Altimeter (MOLA) shaded relief data, Knapmeyer et al. (2006) had constructed a Martian seismicity model that predicts up to 25 seismic events per year with moment magnitudes greater than four corresponding to seismic moments $\geq 1.26 \times 10^{15}$ N m. Most of these events are expected to occur near the Tharsis rise, but other seismic centers may be located south of Hellas and north of Utopia Planitia (**Figure 17**).

10.02.8.6 Future Exploration

The deployment of seismometers will be central to future missions to Mars that attempt determination of the planet's gross interior structure (Dehant et al., 2000, 2012; Grott et al., 2013; Gudkova et al., 2014; Lognonné et al., 2000). Seismological observations would benefit from greatly improved performance of very broadband seismometers combined with new seismic analysis methods based on the cross correlation of seismic noise recorded by two separate seismic stations on Mars and joint seismic/orbiter detection of meteoroid impacts (Dehant et al., 2012). In a similar fashion, radio science tracking of surface stations would improve considerably by using interferometric methods based on two simultaneous Earth–Mars radio links and multiple landers (Dehant et al., 2012). The seismic and geodetic observations will be augmented by electromagnetic sounding and heat flow measurements. Electromagnetic sounding methods are informative about the electrical conductivity of the Martian mantle, indirectly constraining its composition, temperature, and volatile content (Mocquet et al., 2011). Surface heat flow measurements would provide basic information about the planet's thermal state and the bulk abundance of heat-producing elements (Dehant et al., 2012; Grott et al., 2013), thereby helping to test the chondritic hypothesis. Tide-induced gravity variations raised by Phobos also may permit probing of the deep Martian interior by using a very broadband seismometer (Rivoldini et al., 2009; Van Hoolst et al., 2003). Provided free oscillations of Mars are excited by sufficiently large seismic events or atmospheric pressure variations, seismic data acquired by a single broadband instrument alone could be used to infer the radial distributions of density and seismic velocities and the radius of the Martian core (Gudkova et al., 2014).

10.02.9 Venus

Venus, with a radius of 6051.8 km, is only slightly smaller than Earth, but the small size difference may have important consequences for the planet's interior.

10.02.9.1 General

Unlike Earth, Venus has no magnetic field (Donahue and Russell, 1997; Phillips and Russell, 1987; Russell, 1980). This is likely a consequence of the smaller pressure at the center of

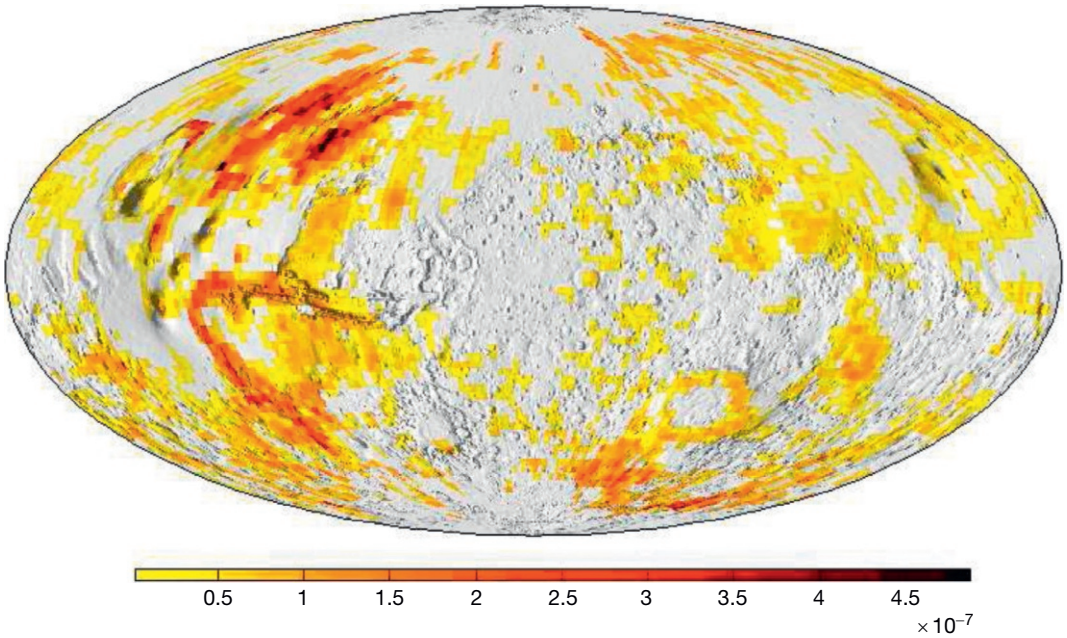

Figure 17 Global distribution of quake probability based on the distribution of extensional and compressional faults on Mars in units of faults per km^{-2}, irrespective of geologic age. Adapted from Knapmeyer M, Oberst J, Hauber E, Wählisch M, Deuchler C, and Wagner R (2006) Working models for spatial distribution and level of Mars' seismicity. *Journal of Geophysical Research* 111: E11006, http://dx.doi.org/10.1029/2006JE002708, with permission American Geophysical union; Copyright 2006.

Venus compared with the pressure at the center of the Earth's core. Because of the lower pressure, it is possible that Venus' core has not yet cooled sufficiently to initiate inner core growth, but has cooled enough to prevent the operation of a purely thermally driven dynamo (Stevenson et al., 1983). Venus' lack of a magnetic field could also be due to its lack of plate tectonics, perhaps indicative of a sluggish form of mantle convection that is unable to cool the core efficiently enough to initiate thermal dynamo action (Nimmo and Stevenson, 2000). Still another possibility, though probably unlikely, is that the core of Venus has solidified enough that a dynamo cannot operate in the remaining liquid outer shell (Arkani-Hamed, 1994). Another consequence of Venus' slightly smaller size compared with Earth is that the perovskite–postperovskite phase transition that occurs near the base of the Earth's mantle may not occur in the Venusian mantle. If the core were to contain less light elements than the Earth's core, however, the Venusian mantle could be even deeper than that of the Earth.

10.02.9.2 Interior Structure

The discussion earlier tacitly assumed that the structure of the Venusian interior is similar to that of the Earth, that is, that Venus is basically a three-layer body with a metallic core surrounded by a rocky mantle, which is in turn surrounded by a compositionally distinct rocky crust. The basic structure of Venus is illustrated in Figure 18. However, the structure of the Venusian interior is a matter of some guesswork because we do not know the MoI of the planet, and though spacecraft have visited Venus and landed on its surface, we have not yet seismically probed its interior. Because of the high pressure (~95 bars) and temperature (~737 K) at the surface of Venus (Seiff, 1983), a seismic experiment is probably far into the future. Venus' MoI is also something we will not know anytime soon. Venus lacks a moon to force a precession of the planet's retrograde spin axis, but the torque on the solar-induced tide forces a free precession ranging from 44.1 to 45.6″ $year^{-1}$ and a variation of obliquity, or wobble, estimated at about 1.1″ $year^{-1}$ (Yoder, 1997). Nevertheless, Venus is such a large terrestrial planet and would be heated so thoroughly upon accretion that differentiation into an Earthlike structure is all but inevitable. The extensive basaltic plains on Venus (Basilevsky et al., 1992; Campbell et al., 1997; Surkov, 1983; Weitz and

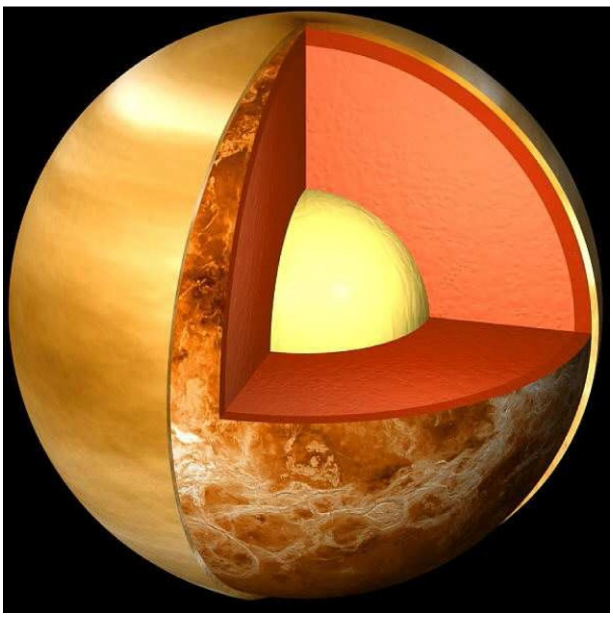

Figure 18 Cutaway view of the interior of Venus. © Calvin J. Hamilton.

Basilevsky, 1993) are evidence that it has differentiated a crust; it is even possible that plateau-like highlands such as Alpha Regio represent compositionally distinct pieces of crust.

Doppler radio tracking data of the Magellan and Pioneer Venus spacecraft have provided basic information about the planet's mass ($GM = 324858.6 \pm 0.014$ km^3 s^{-2}, G is the gravitational constant), gravitational field, and tidal Love number k_2 (Sjogren et al., 1997). The Love number k_2 is determined from the time variations in the gravitational coefficients $C_{2,2}$ and $S_{2,2}$ at the solar period. Konopliv and Yoder (1996) had found $k_2 = 0.295 \pm 0.066$, a value consistent with a liquid core (Yoder, 1997). A 180 degree and order spherical harmonic model of the Venusian gravity is given in Konopliv et al. (1999). Magellan radar altimetry data have been used to produce the 360 degree and order spherical harmonic model of Venus' topography presented in Rappaport et al. (1999) (see **Chapter 10.05** in this volume).

10.02.9.3 Composition

The predominantly basaltic nature of Venus' surface is suggested by the geochemical data obtained by the Venera and Vega landers and the morphology of the widespread volcanic landforms (Grimm and Hess, 1997). The K/U and K/Th ratios of Venusian samples are similar to those obtained for terrestrial volcanics, SNC meteorites, and Martian samples. The variation of the K/U ratios at the seven landing sites is relatively narrow within a factor of three of each other implying that the volatile-refractory element inventory of Venus is comparable to that of Earth and Mars but different from those of the Moon. The major oxide compositions of Venusian rocks are broadly consistent with those of basaltic rocks so that it is reasonable to assume that the crust is largely basaltic (Grimm and Hess, 1997). The gravity and topography data can be analyzed to provide information on the average thickness of the crust; estimates lie in the range 20–50 km (Grimm and Hess, 1997; Nimmo and McKenzie, 1998). The crust is thicker (45–85 km) beneath the plateau highlands (Alpha, Ovda, Thetis, and Tellus Regiones) (Moore and Schubert, 1997) compared with other regions. The basalt–eclogite phase change limits the crustal thickness to about 50 km for moderate conductive geotherms of >5–10 K km^{-1} (Grimm and Hess, 1997). The Venusian gravity and topography data have also been used to infer values for the thickness of the planet's thermal lithosphere and its elastic upper layer. Estimates of lithosphere thickness vary between about 200 and 400 km with thinner lithosphere beneath volcanic highlands (e.g., Atla and Beta Regiones) (Herrick et al., 1989; Kucinskas and Turcotte, 1994; Moore and Schubert, 1997; Phillips, 1994; Simons et al., 1994; Smrekar, 1994). Lithospheric thinning beneath the volcanic rises could have been caused by mantle plumes. There is buoyant sublithospheric mantle beneath the volcanic rises (Moore and Schubert, 1997). The top part of the lithosphere that behaves elastically is only about 30 km thick (McKenzie and Nimmo, 1997). Unlike on Earth, gravity anomalies correlate with high topography on Venus.

10.02.9.4 Tectonism

Pioneer Venus radar, Earth-based radar observations, Venera 15–16 orbital imaging radar, and Magellan radar images have provided views of the surface of Venus unimpeded by the global cloud cover that prevents visual observation. These views, together with the topography and gravity data, reveal the nature of Venusian tectonism and volcanism. On Earth, the global oceanic rift system and the arcuate ocean trenches are the primary surface manifestations of plate tectonics. The almost total absence of these features on Venus has led to the conclusion that active plate tectonics is not occurring on Venus (Kaula, 1994; Kaula and Phillips, 1981). At the present time, Venus is a one-plate planet. Nevertheless, there are tectonic features on Venus that resemble major tectonic features on Earth. Beta Regio, a volcanic highland, has many of the features of a continental rift on Earth. It has a domal structure with a diameter of about 2000 km and a swell amplitude of about 2 km. It has a well-defined central rift valley with a depth of 1–2 km, and there is some evidence for a three-armed planform (aulacogen). Alta, Eistla, and Bell Regiones have similar rift zone characteristics (Grimm and Phillips, 1992; Senske et al., 1992). Aphrodite Terra with a length of some 1500 km is reminiscent of major continental collision zones on Earth, such as the mountain belt that extends from the Alps to the Himalayas. Ishtar Terra is a region of elevated topography with a horizontal scale of 2000–3000 km. A major feature is Lakshmi Planum, which is an elevated plateau similar to Tibet with a mean elevation of about 4 km.

This plateau is surrounded by linear mountain belts, Akna, Danu, Freyja, and Maxwell Montes, reaching elevations of 10 km, similar in scale and elevation to the Himalayas (Kaula et al., 1997).

10.02.9.5 Dynamics

The impact crater population on the surface of Venus has been used to infer a mean surface age of several hundred to as much as 800 My (Herrick et al., 1997; McKinnon et al., 1997). It has been proposed that the relatively young age of Venus' surface was set in a global volcanic resurfacing event and that relatively little volcanism has occurred since (Basilevsky et al., 1997; Schaber et al., 1992). The resurfacing event could be the means by which Venus expels its heat. One way this could happen is the global foundering of a thick, relatively cold, and heavy lithosphere and its replacement by the relatively hot underlying mantle (Turcotte, 1993). Such events might have occurred episodically throughout Venus' history. Between such events, the lithosphere would thicken but Venus would have no efficient way, like plate tectonics on Earth, to expel its heat. Instead, the heat building up in the interior during the quiescent period would be lost in the mantle overturn when the lithosphere thickened enough to become gravitationally unstable. The initiation of such an event might be evident today on Venus' surface in the form of large coronae. Coronae are quasi-circular features, 100–2600 km in diameter, with raised interiors and elevated rims, often with annular troughs (Stofan et al., 1997). Mckenzie et al. (1992) and Sandwell and Schubert (1992a,b) had argued that the perimeters of several large coronae on Venus, specifically Artemis, Latona, and Eithinoa, resemble terrestrial subduction zones in both planform and topography. Artemis chasma has a radius of curvature similar to that of the South Sandwich subduction zone on the Earth. Sandwell and Schubert (1992a) proposed that the large coronae

are incipient circular subduction zones. The foundering lithosphere is replaced by ascending hot mantle in a manner similar to back-arc spreading on the Earth. A single global resurfacing event for Venus has been challenged by Hauck et al. (1998). They argued that the interpretation of the Venusian crater distribution is nonunique, and they identified some units in the volcanic plains that have a spread in age of about 0.5 Gy.

Observations by Venus Express, a European Space Agency mission in orbit around Venus since April 2006, has provided evidence of geologically recent volcanism. The instruments on Venus Express look mainly at the planet's atmosphere, but radiation emitted from the surface at certain wavelengths in the near-infrared reaches the spacecraft through the thick carbon dioxide atmosphere and provides information about surface properties. In this way, the visible and infrared thermal imaging spectrometer on Venus Express mapped the distribution of thermal emissivity over Venus surface (coverage was not complete). Anomalously high values of emissivity were observed at the three hotspots Imdr, Themis, and Dione Regiones (areas analogous to Hawaii, with volcanism, broad topographic rises, and large positive gravity anomalies suggesting mantle plumes at depth). The emissivity anomalies are interpreted to be associated with geologically young lava flows that have experienced relatively little surface weathering (Smrekar et al., 2010). These authors estimate the flows to be younger than 2.5 million years and probably much younger, about 250 000 years or less, indicating that Venus is actively resurfacing.

Because Venus lacks plate tectonics, convection in its mantle is different from the style of convection in the Earth's mantle. Venusian mantle convection occurs in the sluggish or stagnant lid regime, that is, it is confined below the lithosphere or nearly rigid lid (Schubert et al., 1997). This form of convection is less efficient at transporting heat than is the plate tectonic regime with consequent implications for the thermal history of the planet and the dynamics of its core, as noted earlier. Mantle convection in Venus may be unable to establish a near-equilibrium with its internal heat sources resulting in the episodic overturning of its mantle and global resurfacing. Enhanced core cooling would occur during such an event with the possible initiation of a transient dynamo. Heat from the core would be carried away by mantle plumes that could form volcanic rises similar to Atla and Beta Regiones.

10.02.10 Solid Exoplanets

Solid exoplanets with masses of up to about ten Earth masses are thought to have similar interior structures and bulk compositions as the terrestrial bodies in the solar system. Their interiors are thought to be composed of rock-forming elements and metals such as iron, the latter evenly distributed or concentrated in central cores (Elkins-Tanton and Seager, 2008). Unlike for the solar system inner planets, there are even fewer constraints than unknowns in the case of solid extrasolar planets, and even basic interior structure models suffer from inherent nonuniqueness. To address these degeneracies, usually plausible assumptions about their composition and its depth dependence are made (see **Chapter 10.21** in this volume).

Numerical models of planetary interiors using laboratory data on material properties aim at improving the general understanding of their origins, internal evolutions, and present thermal states. In the case of the rocky planets within the solar system, the resultant radial profiles are required to be consistent with geophysical observations and cosmochemical evidence for the compositions of crust, mantle, and core (Mocquet et al., 2011). For rocky exoplanets, the numerical models have to be consistent with the observed planetary masses and radii. Calculated models have been used to derive mass–radius relationships for exoplanets assuming a range of different mineralogical compositions to gain insight into the interior structure and possible bulk compositions of these planets (Fortney et al., 2007; Grasset et al., 2008; Seager et al., 2007; Sotin et al., 2007; Swift et al., 2012; Valencia et al., 2006, 2007; Wagner et al., 2011; Zeng and Sasselov, 2013). Principal uncertainties mainly arise from the extrapolation of an equation of state to high pressures owing to the lack of reliable experimental data in the warm dense matter regime in the pressure range of 200 GPa–10 TPa, whereas the surface temperature and internal thermal state of a massive rocky exoplanet are less important for its radial density distribution (Seager et al., 2007). Nevertheless, the latter are expected to have severe consequences for rheological properties and geodynamic processes. Furthermore, scaling laws for key physical and chemical properties have been obtained (Stamenković et al., 2012; Valencia and O'Connell, 2009; Wagner et al., 2012), which are essential for a better understanding of global planetary processes controlling the general evolution of a planetary body and its astrobiological potential to be life-sustaining.

Figure 19 shows modeled mass–radius relationships in comparison with the relatively large (1–σ) error bars obtained for low-mass planets to date (Wagner, 2014). For the smallest planets, radii appear to be better constrained than masses. These planets are usually detected by space missions (CoRoT and Kepler) providing photometrically accurate light curves, hence radii, but the target objects are often too faint to allow for an accurate mass determination. The knowledge of mean planet density is foremost dependent on the quality of the stellar mass and radius determinations that feeds into the determinations of planetary mass and radius. One of the main goals of future missions is thereby to provide highly precise and accurate measurements of the planet host stars' characteristics, in particular their radii, masses, and ages (Rauer et al., 2014).

10.02.11 Summary and Outlook

The terrestrial planets Mercury, Venus, Earth, and Mars have low masses, small radii, and large densities in comparison with the giant planets in the outer solar system. This is also true for terrestrial-type bodies like the Moon and some of the outer planet satellites, and it provides important clues on their bulk compositions. Rotational, gravitational, and magnetic field observations indicate that the interiors of these bodies are strongly differentiated and subdivided like that of the Earth into iron-rich cores, silicate mantles, and rocky crusts derived from partial mantle melts. Isotope data reveal that the cores and the primary crusts formed early and rapidly. Geodetic observations of the rotational state and/or tidal response suggest that the interiors are warm enough to maintain liquid outer core shells or entirely liquid cores. For Mars, Venus, and Earth, mantle pressures are sufficient to permit mineral

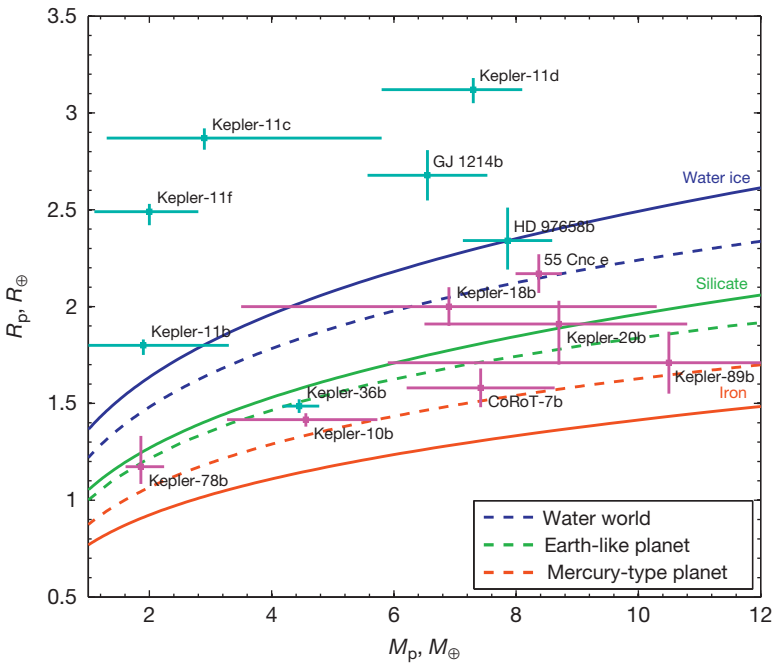

Figure 19 Mass–radius diagram for planets with different bulk compositions compared to currently known low-mass exoplanets in Earth units. Equilibrium surface temperatures are divided into two domains from 500 to 1000 K (cyan blue) and 1000–2000 K (magenta). While the solid curves denote homogeneous, self-compressible solid spheres of water ice, silicate rock, and iron, respectively, the dashed curves exhibit differentiated models of intermediate bulk compositions. Reproduced from Wagner FW (2014) *The Physical State of Rocky Exoplanet Interiors*. Dissertation, Westphalian Wilhelms-University, Munster.

phase transformations from olivine and pyroxene assemblages to spinel or even perovskite and postperovskite phases. Since the phase transition depths also depend on the ambient temperature and the iron content of the mantle rocks, future seismological observations complemented by electromagnetic induction data and heat flow measurements have the potential to provide additional information on the thermal states and compositional differences of the terrestrial planets. Single-plate planets, the Moon, Mercury, Mars, and Venus, are believed to be cooling by lithospheric thickening, while the deep interior remains relatively warm. It is likely, therefore, that due to the progressive cooling of the planet's outer portion, thermoelastic stresses will be occasionally released at preexisting faults, thereby causing local seismic activity at a level detectable by seismometers. The discovery of rocky exoplanets relies on current detection limits of ground-based observational methods. Structural models of solid exoplanet interiors can be constructed by using equations of state for the radial density distribution, which are compliant with the thermodynamics of the high-pressure limit. The modeling results imply that mass–radius relationships are robust and can be used to classify low-mass exoplanets such as CoRoT-7b and Kepler-10b in terms of their bulk compositions.

Acknowledgments

We thank Matthias Grott, Tamara Gudkova, Martin Knapmeyer, Jürgen Oberst, Heike Rauer, Attilio Rivoldini, Alexander Stark, Teresa Steinke, Diana Valencia, and Frank W. Wagner for their helpful discussions. 10.03.1 Introduction

One hundred and twenty five years have passed since Von Rebeur-Paschwitz (1889) first detected a remote seismic event, and almost 70 years have passed since the creation of the first mean seismic models of the Earth based on body-wave travel times (Bullen, 1947). As a result, seismology is now generally accepted as the geophysical tool best able to determine the internal structure of a planet. Seismology has also led to a revolution in Earth science, especially since the advent of three-dimensional (3D) tomographic models of the Earth's mantle (e.g., Dziewonski et al., 1977; Woodhouse and Dziewonski, 1984) that depict major discontinuities in the mantle and reflect convection patterns and lateral variations in its temperature or mineralogy. For a complete and extensive description of seismology as applied to Earth, see volume 1 of *Treatise on Geophysics: Deep Earth Seismology*.

We are a long way from achieving this level of seismological knowledge for bodies other than Earth, however, and the seismic identification of the Earth's core, realized by R.D. Oldham one century ago (Oldham, 1906), remains the only example of detecting seismic waves refracted by a planetary core. The situation is similar for the detection of a planet's normal modes, with the first successful detection of normal modes on Earth following the great Chilean Earthquake in 1960 (e.g., Benioff et al., 1961). As a consequence (see the other chapters of this Treatise), we currently have no precise measurements of the core radius of the Moon or Mars; no direct information on the martian mantle structure, including its discontinuities; no definitive direct measurements of martian seismic activity; and no direct measurement of the mean crustal thickness of Mars.

The use of seismometers in planetary exploration was proposed early in the history of space missions (e.g., Press et al., 1960). Yet, almost 52 years after the launch of the first seismometer to a telluric body (Ranger 3, in 1962), planetary and small-body seismology has only been successfully studied on Earth's Moon. The Apollo program deployed a network of four seismic stations on the Moon (Latham et al., 1969, 1970a,b, 1971), as well as the short-lived Apollo 11 seismometer for passive monitoring, and three active seismic experiments were conducted during the missions of Apollo 14, 15, 16, and 17 (Kovach and Watkins, 1973a; Watkins and Kovach, 1972). The thirteen other extraterrestrial seismometer experiments that launched successfully never recorded any quakes (see **Table 1**). These nonyielding lunar missions include the seismometers (Lehner et al., 1962; Press et al., 1960) onboard the 3 Ranger lunar probes, which were lost with their missions in the early 1960s; the seismometer lost with the cancellation of the Apollo 13 Moon landing; and the gravimeter onboard the last Apollo 17 mission, which failed to operate despite expectations that it would extend the work of the previous Apollo instruments by providing long-period (LP) seismic data. Several attempts have been made to conduct seismic experiments on Mars. Two

Table 1 Summary and history of planetary seismology experiments delivered to launch

Mission	*Launch*	*Major mission events*	*Instrument description*	*Seismometer deployment*	*References*
Ranger 3	1962-01-26	Failure due to the booster. Moon missed	Vertical axis seismometer, with a free frequency of 1 Hz (mass: 3.36 kg)	Seismometer in a lunar capsule designed for a 130–160 km h^{-1} landing. Batteries powered for 30 days of operation	Lehner et al. (1962)
Ranger 4	1962-04-23	Failure of spacecraft central processor. Moon crash			
Ranger 5	1962-10-18	Failure in the spacecraft power system. Moon missed			
Apollo 11	1969-7-16	Successful installation. Powered by solar panel, worked during the first lunation and stopped after 21 days	Passive seismic experiment (PSE). Triaxis long-period (LP) seismometer and one vertical short-period (SP) seismometer, with resonance periods of 15 and 1 s, respectively (mass: 11.5 kg, power: 4.3–7.4 W)	Installation performed by crew. Seismometers were manually leveled and oriented with bubble level and sun compass. A sun protection/thermal shroud was covering the instruments. Power was delivered by a plutonium radioisotope thermoelectric generator for A12–14–15–16	Latham et al. (1969, 1970a,b)
Apollo 12	1969-11-14	Successful installation of a network of 4 stations. Except for the Apollo 12 SP seismometer and Apollo 14 vertical LP seismometer, all operated until the end of September 1977, when all were turned off after a command from the Earth. 26.18 active station years of data collected			
Apollo 14	1971-01-31				
Apollo 15	1971-07-26				
Apollo 16	1972-04-16				
Apollo 13	1970-4-11	Moon landing aborted. No installation of the PSE experiment, but the lunar crash of the Apollo 13 Saturn-IV upper stage was recorded by the A12 PSE			
Apollo 14	1971-01-31	Successful installation and operation of the active seismic experiments. Seismic sources were thumper devices (A14, A16) containing 21 (A14) and 19 (A16) small explosive sources and a rocket grenade launcher with three sources exploding up to 900 m on A16. Eight sources were used containing up to 2722 g of explosive and deployed up to about 2800 m by astronauts on A17	String of three geophones on A-14 and A-16 and on four geophones on A-17. Frequency was 3–250 Hz	Geophones were anchored into the surface by short spikes as they were unreeled from the thumper/geophone assembly	Watkins and Kovach (1972), Kovach and Watkins (1973a,b)
Apollo 16	1972-04-16				
Apollo 17	1972-12-07				
Apollo 17	1972-12-07	Deployment of the Lunar Surface Gravimeter. The gravimeter was unable to operate properly due to an error in the design of the proof mass	Gravimeter designed for gravity-wave detection. Additional LP vertical seismic output (10^{-11} lunar g resolution) for free oscillation detection, with a 16-Hz sampling	Installation performed by crew	Weber (1971), Tobias (1978)
Viking Lander 1	1975-08-20	Successful landing but instrument failure	SP instrument, with an undamped natural period of 0.25 s, a mass of 2.2 kg, a size of $12 \times 15 \times 12$ cm and a nominal power consumption of 3.5 W	The seismometer was installed on the Lander platform. No recentering was necessary, because the 3-axis seismometer had been designed to function even when tilted to up to 23°	Anderson et al. (1977a,b)
Viking Lander 2	1975-09-09	Successful landing and 19 months of nearly continuous operation. Too high wind sensitivity associated to the elastic recovery of the Viking

		landing legs to the loading of the station by pressure fluctuations induced by the wind			
Phobos 1-2	1988-07-07 1988-07-12	Phobos 1 was lost during transfer to Mars and Phobos. Contact with Phobos 2 was lost just before the final phase of lander deployment, after Mars orbit insertion		Instrument onboard the long-service lander	Surkov (1990)
Mars 96 Small surface stations	1996-11-16	Failure of the block-D propulsion system in parking orbit. Earth re-entry. Two small stations and two penetrators lost	LP vertical-axis seismometer (0.1–4 Hz, 0.405 kg for the sensor) combined with a magnetometer. 55 mW of power	Seismometer in the small surface station. Semi-hard landing (200 g to 20 ms). Nominal operations for 1 martian year with nearly continuous operation with internal batteries for the first 90 days	Lognonné et al. (1998a)
Mars 96 Penetrators			High-frequency seismometer (10–100 Hz, 0.3 kg, 20 mW)	Seismometer in the penetrator. Hard landing. Nominal operations for 1 martian year	Khavroshkin and Tsyplakov (1996)
Rosetta	2004-03-04	Landing on the comet 67P/Churyumov-Gerasimenko planned a few months after rendezvous, expected on 2014-11-14	CASSE/SESAME experiment: three triaxial piezoelectric accelerometers and three piezoelectric active sources	Sources and accelerometers are housed within the landing gear's feet	Seidensticker et al. (2007)

Experiments that lead to the detection and interpretation of quake data are indicated by bolded names in the Mission column. The bolded and italicized name indicates a successful deployment without clear event detection or interpretation. The claimed detection of microseismic activity during the short-lived Venera lander mission might complete this list. All dates in the table are expressed as year-month-day.

seismometers were deployed in 1976 by the Viking mission; however, one was never unlocked, and the other provided no convincing event detection after 19 months of nearly continuous operation (Anderson et al., 1977a,b). Twenty years later, both Optimism seismometers (Lognonné et al., 1998a) onboard small surface stations (Linkin et al., 1998) and the Kamerton short-period (SP) seismometers (Khavroshkin and Tsyplakov, 1996) onboard two penetrators were lost as part of the Mars 96 mission. Another 20 years will now pass before the return of the first data from the NASA InSight mission, which is planned to launch and land in 2016. Finally, for small bodies, the two SP seismometers onboard the Phobos landers (Surkov, 1990) never reached Phobos, and the SESAME/CASSE (Seidensticker et al., 2007) acoustic experiment, which is onboard the Rosetta lander en route to comet 67P/Churyumov–Gerasimenko, is now the only active experiment that might gather, in late 2014 early 2015, some seismic signals on a solid body other than Earth.

The seismometers developed for early missions used techniques that were pioneering, even compared to contemporary state-of-the-art Earth instruments. The Ranger seismometer was proposed by Press et al. (1960) and designed by the California Institute of Technology (Lehner et al., 1962) for the first missions to land on the Moon, and it was built to survive up to a 3000 g shock ($1\ g = 9.81\ m\ s^{-1}$). The Ranger device was a vertical-axis seismometer with a free frequency of 1 Hz and a mass of 3 kg, and it was one of the first digital instruments. Although the three Ranger probes failed, the technology was reused for operating one of the first terrestrial digital seismometers at Caltech (Miller, 1963). A new experiment was then proposed for the Surveyor mission, including a 3-axis LP seismometer and an SP vertical-axis seismometer, built at the Lamont Doherty Geological Observatory (Sutton and Latham, 1964), with a total mass of 11.5 kg. These models were later descoped to a single SP vertical-axis seismometer (Sutton and Steinbacher, 1967) before being canceled for the Surveyor program. As a result, this technology was not implemented until the Apollo missions to the Moon, and it was reused in terrestrial seismology, notably in the first ocean-bottom seismometers deployed in the 1970s. The deployment of seismometers was also planned for the Soviet Lunakhod, using a 1-Hz vertical fused quartz seismometer. This experiment was cancelled, however (Osika and Daragan, personal communication).

In July 1969, the Apollo 11 mission installed the first operational seismometer on a planetary body other than the Earth. The passive seismic experiment (PSE) consisted of a 3-axis LP seismometer with a resonance period of 15 s, as well as one vertical SP seismometer with a resonance period of 1 s. The total mass of both instruments and the electronic and thermal control module was 11.5 kg, and the power

consumption was between 4.3 and 7.4 W (Latham et al., 1969, 1970a,b). These seismometers were extremely sensitive. In flat-response mode, the LP seismometer was capable of detecting a displacement of 3×10^{-10} m at frequencies of 0.1–1 Hz, and in peaked-response mode, it could detect a displacement of 0.5×10^{-10} m at 0.45 Hz. For its part, the SP seismometer could detect a displacement of 0.5×10^{-10} m at 8 Hz. **Figure 1** shows the corresponding nominal acceleration response curves, as well as the noise recorded on the Moon. Practically, these instruments were unable to detect the continuous microseismic noise of the Moon, instead recording only the significant background noise associated with thermal effects in the shallow subsurface around sunrise and sunset. The Moon noise recorded on the vertical-component seismometer was as low as 10^{-10} ms^{-2} Hz$^{-1/2}$ at frequencies in the range 0.1–1 Hz (Earth's microseismic peak). This level of sensitivity allowed the detection of about 13 050 seismic signals between July 1969 and September 1977 (a mean of about four quakes per day), and many more unreported events were recorded by the SP instruments. The most recent LP event catalog is available online at the University of Texas, at ftp://ftp.ig.utexas.edu/pub/PSE/catsrepts/ (Nakamura et al., 2008).

The first PSE experiment was powered by solar panels, and it survived the first lunar night, but ultimately failed due to high temperatures during the second lunar day (Latham et al., 1969, 1970a,b). Subsequent seismometers used a radioisotope thermoelectric generator that supported continuous day and night operation. A seismic network of four stations (**Figure 2**) was installed by Apollo 12, 14, 15, and 16, and, as discussed in multiple lunar and seismological reviews, this network has been critical for understanding the internal structure of the Moon (e.g., Hood, 1986; Hood and Zuber, 2000; Lognonné,

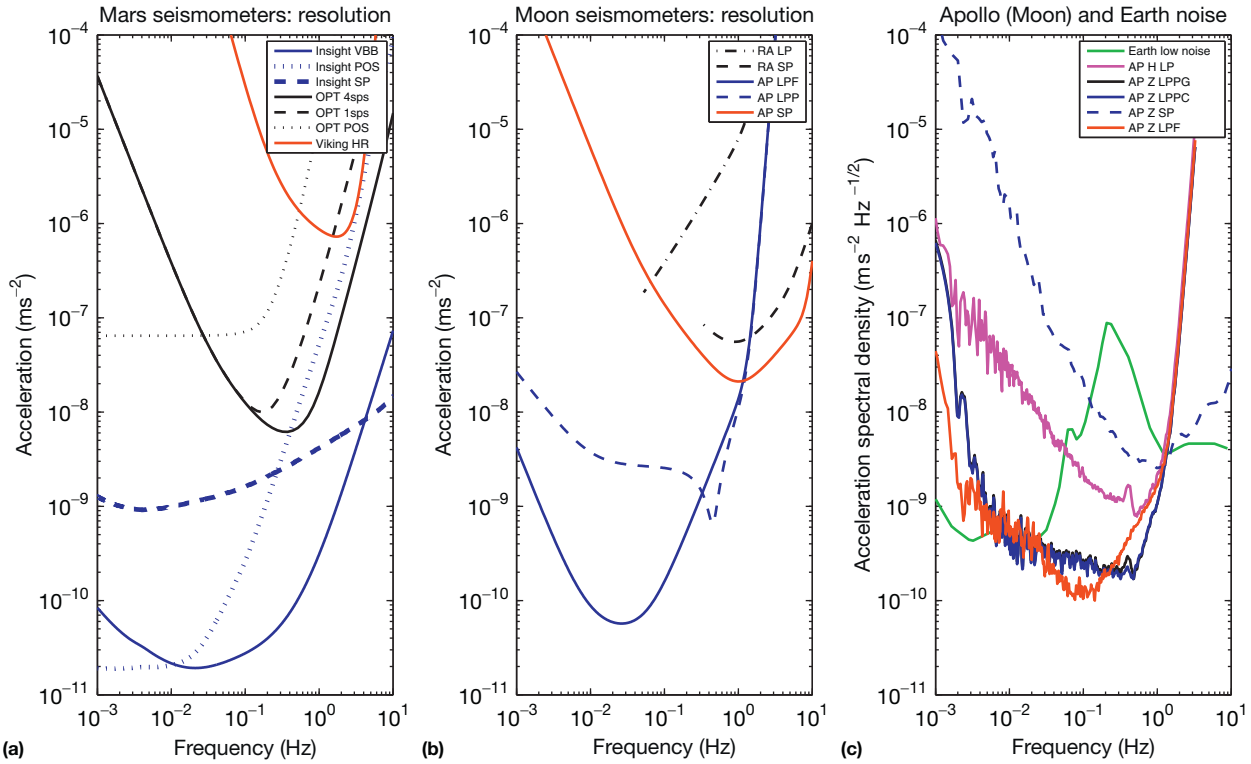

Figure 1 Response curves of the past Mars (a, left) and Moon (b, middle) seismometers. (a) The resolutions of the Viking seismometer in the high data rate mode (Viking HR) and the Optimism seismometer in the long period position mode (OPT POS), the velocity mode at 1 sample per second (OPT 1sps), and the velocity mode at 4 samples per second (OPT 4sps). The figure also shows the expected resolution of the InSight seismometers, which is defined here as the RMS in one octave bandwidth. The blue continuous and blue dashed curves are the velocity flat and acceleration flat outputs of the very broad band instrument (InSight VBB and InSight POS), while the long dashed blue one is the velocity flat output of the SP instrument (InSight SP). VBB components are sensitive to acceleration along an oblique about 30° with respect to horizontal, while the SP components are either vertical or horizontal. At 1 Hz, the expected resolution of the InSight VBB sensor is expected to be 10^3 better than Viking. (b) The Moon, with the long-period (RA LP) and short-period (RA SP) analog outputs produced by the Ranger seismometer, the flat mode (AP LPF) and peaked mode (AP LPP) of the Apollo LP seismometer, and the SP seismometer (AP SP). The transfer functions shown in the figure are generic. (c) Different sources and levels of seismic noise on the Moon. The noise levels recorded on the Moon by the different channels of the Apollo seismometers are compared with the Earth-based low noise model of Pedersen (1993). The noise levels are from the Apollo 12 instrument for the vertical LP flat component (AP Z LPF) and from the Apollo 14 instrument for the vertical SP component (AP Z SP). These noise levels likely represent an upper estimate of the Moon noise and may be related to the instruments. For the other components, note that the peaks near 0.45 Hz of the peaked vertical records (AP Z LPPG) and peaked horizontal records (AP H LP) might be related to differences between the Apollo 12 transfer function at the time of the recording and the preflight generic transfer function. The noise corresponding to the curve AP Z LPPC is obtained by changing the feedback parameters for the transfer function of the instrument in order to minimize the peak in the noise PSD. Changes are on the order of 10% for the parameters K2 and h. See the Apollo transfer function at http://darts.jaxa.jp/planet/seismology/apollo/The_Apollo_Seismometer_Responses.pdf).

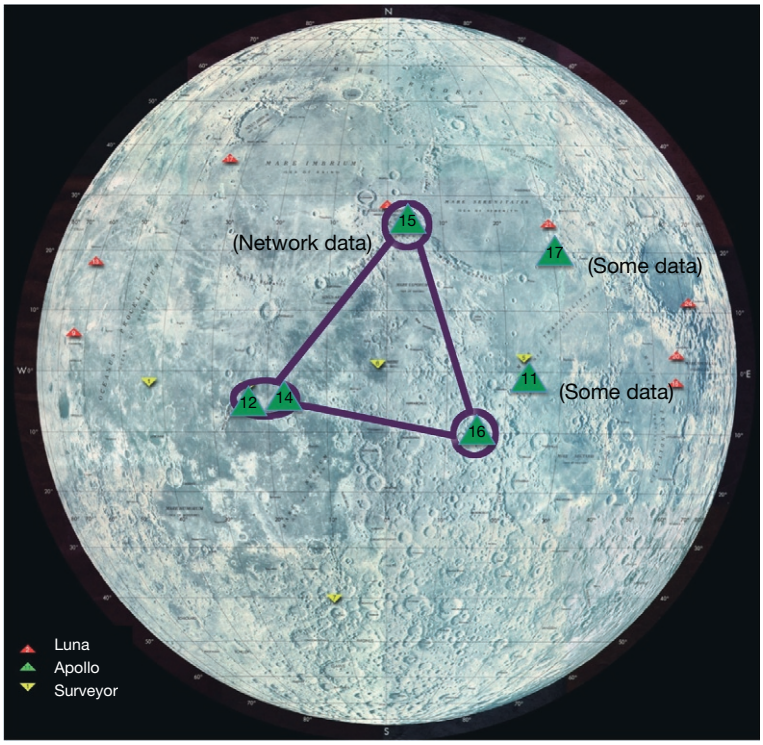

Figure 2 Configuration of the Apollo seismic network, with each Apollo seismometer represented by a green triangle. A12 is in the Oceanus Procellarum area at 3.01° S, 23.42° W. A14 is located near the crater Fra Mauro at 3.64° S, 17.47° W. A15 is at the foot of the Apennine Mountains at 26.13° N, 3.63° E, and A16 is just north of the crater Dolland at 8.97° S, 15.50° E. Note that all stations were on the near-side, making core seismic studies almost impossible. Additional seismic data have also been recorded at the Apollo 11 and Apollo 17 sites. The soviet Luna and early US Surveyor landing sites are given for completeness. Base map credit: NASA.

2005). Given its low seismic noise, the Moon has also been proposed as a good place for detecting astrophysical gravitational waves (e.g., Gusev and Kurlachev, 1976; Weber, 1960), and a gravimeter designed for that purpose was installed onboard Apollo 17. This gravimeter failed to operate properly, however, due to a design failure. More recently, the possibility of strange quark matter detection (Banerdt et al., 2006) has been proposed, reigniting interest in the Moon as a site for the placement of seismic or gravity sensors for astrophysics research.

In this chapter, we summarize the experimental and seismological data in **Section 10.03.2**. We devote some attention to 1D seismic-velocity models for the Moon's crust and mantle, and we discuss differences among current models, especially with regard to their likely causes and implications. We also explore the current understanding of the Moon's mineralogical structure derived by integrating the Apollo seismic data with other geophysical and petrological constraints, and, in **Section 10.03.3**, we discuss the seismic activity of the Moon in the context of other terrestrial planets.

We address the field of atmospheric seismology in **Section 10.03.4**, including the basic theory behind the coupling of solid-body modes to the atmosphere and ionosphere. We also discuss the giant planets, especially Jupiter, given that, for about 20 years, Earth stations have monitored Jupiter's atmospheric signals associated with continuously excited global oscillations (Lognonné and Mosser, 1993; Mosser, 1995). We then develop a comparative study of atmosphere-interior seismic coupling on Mars and Venus and discuss the prospect of remotely sensed seismology.

Starting with the 1976 deployment of the Viking seismometers, the seismic exploration of Mars has been much less successful than the exploration of the Moon (Anderson et al., 1977a,b). During the initial mission, only the Viking 2 seismometer worked, as the seismometer on Viking 1 lander failed to unlock. The sensitivity of the Viking 2 seismometer was one order of magnitude less than the SP Apollo seismometer for periods shorter than 1 s, and five orders less than the LP seismometer for periods longer than 10 s (see **Figure 1**). No events were convincingly detected during the seismometer's 19 months of nearly continuous operation, and, as shown by Goins and Lazarewicz (1979), this absence of recorded events was probably related to the inadequate sensitivity of the seismometer in the frequency bandwidth of teleseismic body waves, as well as the device's high sensitivity to wind noise (Nakamura and Anderson, 1979). In 1996, the Mars 96 mission was launched, with each of the mission's two small stations (Linkin et al., 1998) carrying an OPTIMISM seismometer in its payload (Lognonné et al., 1998a). The sensitivity of the OPTIMISM seismometer was improved by about two orders of magnitude relative to the Viking seismometers at frequencies of 0.5 Hz, and as a result, the OPTIMISM devices were better adapted to teleseismic body-wave detection. The Mars 96 mission was lost shortly after its launch, however, and the seismic

exploration of Mars remains an outstanding avenue of investigation in solar system science. Thus, determining the seismicity of Mars is the main goal of the InSight NASA mission, which will deploy the first geophysical observatory on the red planet. Two Apollo-class 3-axis seismometers will be deployed by InSight, for both LP and SP detection. The expected performances of these devices are shown in **Figure 1**. Compared to the Apollo seismometers, the InSight seismometers have slightly better resolution, and they will likely be solely limited by the martian environment and possibly microseismic noise. We will return to the discussion of Mars seismology and InSight in **Section 10.03.5**, as it leads the way for future surface-based exploration of other bodies. We will then discuss the current understanding of the martian interior, along with noise levels and other issues relevant to the InSight strategy for marsquake detection.

10.03.2 Lunar Results

10.03.2.1 The Apollo PSE Data

From 1969 to 1977, the Apollo Lunar Surface Experiment Package (ALSEP) recorded the lunar PSE data that now provide a unique and valuable resource for determining the interior structure of the Moon. The Apollo seismic 'network' comprised four stations at Apollo sites 12, 14, 15, and 16. Stations 12 and 14 were about 180 km apart, and, together, they formed one corner of an approximately equilateral triangle, with stations 15 and 16 at the other corners, about 1100 km apart (**Figure 2**). The lunar event catalog (Nakamura et al., 2008) documents 13 058 events recorded by the network. Recorded events exhibit different signal characteristics and originate from five types of sources originally classified as artificial impacts (9), meteoroid impacts (~1700), shallow moonquakes (28), deep moonquakes (~1360), and unclassified events. Many of the originally unclassified events have since been classified as deep moonquakes, with a total of 7084 deep moonquakes identified (as reported in Nakamura et al., 2008).

Compared with terrestrial quakes, moonquakes are small-seismic-moment events, and, as a result, the moonquakes recorded by the Apollo missions generated small signals, often with amplitudes smaller than the microseismic noise on Earth, even in Earth's best seismic vaults. At first, events were visually identified in the lunar data, using hardcopy printouts and overlays of the seismograms recorded at Apollo stations 12, 14, 15, and 16. The criteria used to identify and classify seismic sources included the time interval from the start of a signal to its maximum amplitude (rise time), the dominance of low-frequency versus high-frequency content in the records, and the presence of compressional (P) and shear (S) waves (see review in Lammlein, 1977 and details in Lammlein, 1973 and Lammlein et al., 1974). Shallow events are also referred to in the literature as high-frequency teleseismic events, because of their unusually high frequency content and poor depth location (Nakamura, 1977a, 1980; Nakamura et al., 1974a, 1979). Analyses of data during early ALSEP operations suggested that deep moonquakes have two important characteristics (Nakamura et al., 1980) that were subsequently used to help identify such events. These characteristics are similar waveforms and tidal periodicities in moonquake occurrence times (Ewing et al., 1971; Lammlein, 1977). The main properties of the seismic sources, including seismic moment, stress drop, and rupture times, are given in **Section 10.03.3**. **Figure 3** also shows examples of waveforms recorded at the Apollo stations, according to source type. In general, events become apparent in the seismic readings only after data filtering. Filtering is required because the raw waveform data are dominated by large amplitude signals that result from the expansion and contraction of the thermal Mylar shroud at sunrise and sunset (Duennebier and Sutton, 1974; see Figure 3 of Bulow et al., 2005).

During the Apollo era, digital data were extracted from the complete, continuous PSE records for time windows encompassing identified events, and the digital data were then stored as the 'event' waveform data set. This derived data set and the original continuous records are now available, with documentation, from the IRIS Data Management Center (http://www.iris.edu/dms/nodes/dmc/) and at the ISAS DARTS web site (http://www.darts.isas.jaxa.jp/planet/seismology/apollo/index.html, Nagihara et al., 2011). Recent analyses of the Apollo 17 gravimeter complement the lunar data set with seismic records from the Apollo 17 landing site (Kawamura et al., 2010a,b), including records for deep moonquakes. Although the generic transfer functions of the Apollo seismometer have been published (see, e.g., on ISAS DARTS) and are generally used in most publications, it is possible that aging led to some change in these transfer functions. For example, when corrected with the generic transfer function, the noise spectrum of the Apollo 12 vertical records in peaked mode shows significant peaks near the peaked frequency of about 0.45 Hz (blue curve of the right box of **Figure 1**). These peaks decrease significantly, however, when slight changes are made to some of the transfer function parameters, as when the coil-magnet efficiency and the damping constant of the natural suspension are changed by −6% and −16%, respectively, from their nominal values for the light blue curve. For this reason, time-related changes in seismometer function will be kept in mind when detailed analyses are done on Apollo seismic data, including on the subsurface resonances. Although accurate time-dependent transfer functions can be obtained by processing calibration signals, which were recorded periodically (usually once a week) throughout the experiment, the coefficients of these functions (i.e., gain, pole, and zero) for each of the Apollo instruments throughout the 7 years of operation are not available in the literature.

Later work (Nakamura, 2003) has classified a significant fraction of identified, but previously unclassified, events (Nakamura et al., 1981) and has led to a nearly fivefold increase in the number of cataloged deep moonquakes. Additionally, work by Bulow et al. (2005) showed that the waveform repeatability of deep moonquakes can be exploited to search for additional unidentified events associated with known deep source regions. Implementation of this algorithm led to an approximately 35% increase in the number of events at the nine most seismically active (at the detection level of the Apollo seismometers) source regions (Bulow et al., 2005, 2007). Despite the seemingly large number of lunar seismic events, the poor signal-to-noise ratio for emergent arrivals in most records means that it is only possible to accurately measure arrival times and locate events for a subset of the lunar catalog

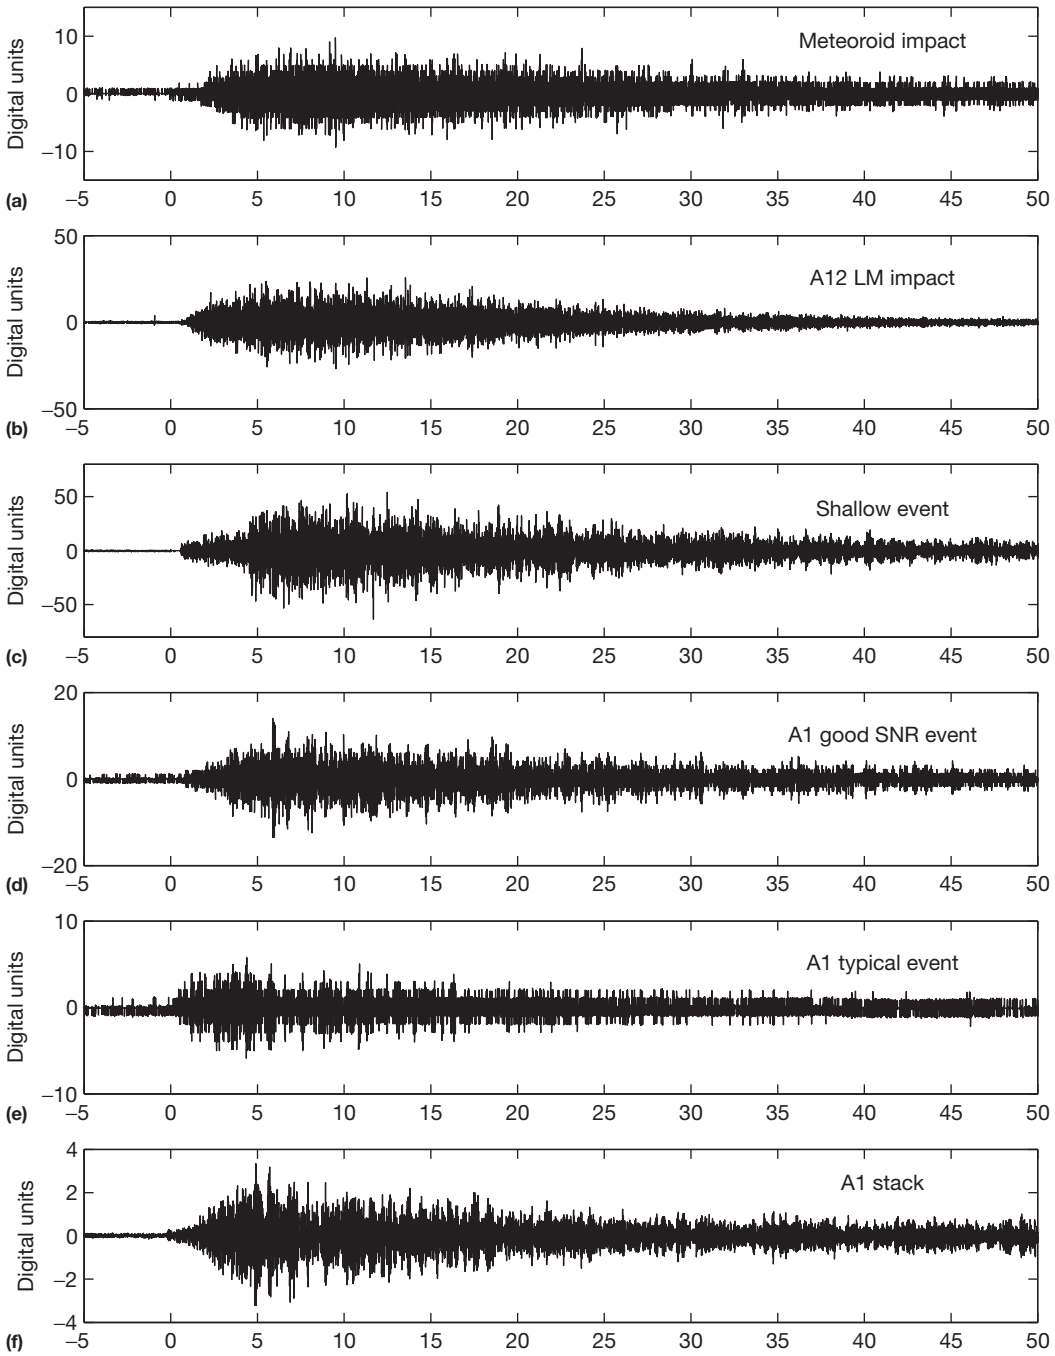

Figure 3 From top to bottom, examples of waveforms for natural impacts (a), artificial impacts (b), a shallow event (c), and deep moonquakes (d–f) recorded on LP channels by the Apollo passive seismic network. All records span 55 min, with the *x*-axis representing time in minutes and the *y*-axis representing digital units. The following characteristics aided the identification of different seismic sources in the Apollo data: (1) The rise time (defined as the time from event onset to maximum signal amplitude) of moonquakes is typically less than that of meteoroids – the rise time in (c), (d), and (e) is approximately 5 min, while the rise time in (a) is approximately 10 min; (2) Deep moonquakes typically have low amplitude and produce poor data quality, as in (e). However, the waveform repeatability of deep moonquakes from distinct source regions allows the use of stacking to improve the signal-to-noise ratio, as in (f).

data (Figure 4). Small event magnitudes and restricted receiver locations mean that events for which travel times can be clearly identified mainly occur on the near-side of the Moon.

The Apollo passive seismic data set has contributed enormously to our understanding of the internal structure of the Moon. The temporal and spatial distributions of lunar seismicity provide constraints on subsurface structure. Of particular importance is the evidence of brittle failure at depths of 700–1200 km, with failures apparently concentrated in the 800–1000-km depth interval. Unfortunately, the small

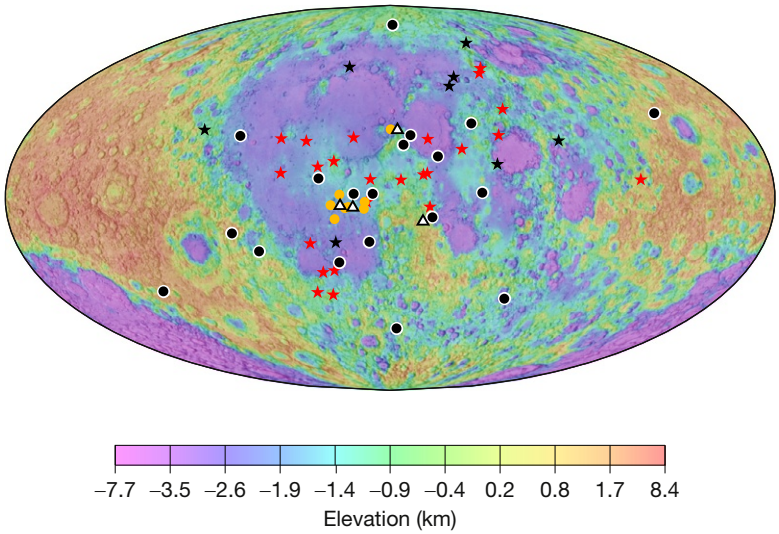

Figure 4 Seismic events located by Lognonné et al. (2003) and used in recent velocity models (Gagnepain-Beyneix et al., 2006; Lognonné et al., 2003). The figure shows Apollo stations 12, 14, 15, and 16 (white triangles), along with the locations of 24 deep-event clusters (red stars), 8 shallow events (black stars), 19 meteoroid impacts (black circles), and 8 artificial impacts (orange circles). The background color map is the Clementine topography (Aitoff equal area projection), shaded using a global digital image map (USGS map I-2769, 2002).

magnitude of these events, combined with the limited number and geographical distribution of receivers, and associated errors in the locations of deep moonquakes (see, e.g., Hempel et al., 2012 for a recent analysis of the location errors), means that it has not been possible to unambiguously establish a focal mechanism for any of the deep moonquakes (Koyama and Nakamura, 1980). Seismic-velocity models for the crust and mantle (see **Section 10.03.2.2**) constrain the physical properties of the lunar interior (including temperature) and provide indirect constraints on mineralogy and the thermal evolution of the Moon. Studies of seismic attenuation indicate a dry lunar mantle (Nakamura and Koyama, 1982). Attempts have been made to investigate lunar normal modes (Khan and Mosegaard, 2001) to constrain the core size and state. However, these have largely been unsuccessful because of the limited bandwidth of the Apollo seismometers (**Figure 1**).

The Moon's shallow structure has received less attention in the literature, but it is of particular interest given the results from the Gravity Recovery and Interior Laboratory (GRAIL) mission (see below). The long coda in the observed waveforms likely result from the combined effects of low attenuation and a highly scattering near-surface layer with low seismic velocity (Latham et al., 1970a; Nakamura, 1976, 1977b). These coda can thus be used to probe the structure of the brecciated upper crustal layer, or megaregolith. Early lunar studies investigated the geological structure in the immediate vicinity of the receivers. For example, Nakamura et al. (1975) estimated regolith thicknesses of a few meters beneath Apollo stations 11, 12, and 15, with an underlying layer displaying P-wave velocities of 250–400 m s^{-1}, and Horvath et al. (1980) calculated seismic-velocity profiles down to a depth of about 200 m. The coda decay can be characterized by the quality factor Q_c (where Q_c^{-1} represents the fraction of energy dissipated per cycle at a given frequency), and, for a lunar module impact at Apollo station 12, Latham et al. (1970a) found $Q_c \sim 3600$, a value much larger than those recorded for terrestrial crustal rocks. Blanchette-Guertin et al. (2012) have undertaken the first systematic survey of the coda characteristics of impacts and moonquakes recorded at all four Apollo passive seismic stations. The results indicate decay times and Q_c increase with depth, and Q_c increases with increasing frequency and epicentral distance for shallow events. The results are consistent with scattering in a global, low-velocity and low-attenuation megaregolith layer with a size distribution of scatterers (blocks) that have more small-scale scatterers than large-scale scatterers. In addition, this study finds that scattering can be intensified locally in one or more frequency bands due to local structure.

In the following section, we discuss attempts to establish seismic velocity profiles for the lunar crust and mantle, and we also highlight GRAIL mission results related to lunar crustal structure. Because of their potential to provide significant insights concerning the lunar interior, these seismic-velocity models have been used for many seismological, mineralogical, and thermal studies of the Moon.

10.03.2.2 Seismic-Velocity Structure: Crust and Mantle

Due to scattering in the lunar seismograms, as well as the limited computational resources of the 1970s, most investigations of the lunar interior have used the arrival times of body-wave phases to investigate plausible 1D models for seismic-velocity structure. This approach, completed using normal modes and surface-wave data, has been applied with great success in terrestrial seismology through a series of efforts leading to the long-standing preliminary reference Earth model (PREM) for Earth's interior structure (Dziewonski and Anderson, 1981) and to the body-wave IASP91 model (Kennett and Engdahl, 1991). Lunar studies use the arrival times of direct P and S waves, picked from seismograms for as many channels and stations as possible. Individual seismograms are used for impacts and shallow moonquakes. For deep moonquake sources, all records of a specific source region are stacked to improve the

signal-to-noise ratio (Lognonné et al., 2003; Nakamura, 1983). Source-to-receiver P- and S-wave travel times depend on the receiver location (known), the source location (generally unknown, though natural impacts occur on the surface, and artificial impact locations are known), the source time (unknown, except for artificial impacts), and the interior velocity structure (unknown). The standard seismological approach involves simultaneously solving for source locations and times, along with interior velocity structure (e.g., Shearer, 1999).

As measured from the lunar seismograms, P- and S-wave arrival times have been either inverted or forward-modeled to estimate lunar seismic-velocity profiles (e.g., Gagnepain-Beyneix et al., 2006; Garcia et al., 2011; Goins et al., 1981b; Khan and Mosegaard, 2002; Khan et al., 2000, 2007; Lognonné et al., 2003; Nakamura, 1983; Nakamura et al., 1976). As the construction of lunar seismic-velocity models has been reviewed elsewhere (Lognonné, 2005), we do not repeat those reviews here. Instead, we restrict our discussion to five 1D models for P- and S-wave velocity based on travel-time data (Gagnepain-Beyneix et al., 2006; Garcia et al., 2011; Goins et al., 1981b; Khan et al., 2007; Nakamura, 1983) and one model derived solely from mineralogical modeling without a priori seismic constraints (Kuskov et al., 2002). Regardless of their forms, all discussed models illuminate the main unresolved questions about lunar interior structure (**Figure 5**).

Figure 5 shows the P- and S-velocity models of Goins et al. (1981b), Nakamura (1983), Khan et al. (2007) (see also Khan and Mosegaard, 2002; Khan et al., 2000), Gagnepain-Beyneix et al. (2006), and Garcia et al. (2011). We have chosen these studies because they are all primarily based on the Apollo seismic data, and they exemplify the state-of-the-art calculations made immediately after the publication of the complete lunar event catalog (Goins et al., 1981b; Nakamura, 1983), the alternative modern probabilistic techniques applied to the early travel-time data set (Khan et al., 2007), recent revised travel-time picks and derived velocity models (Gagnepain-Beyneix et al., 2006; Lognonné et al., 2003), and additional constraints on the deep moon structure based on transversely polarized, reflected S waves (Garcia et al., 2011).

The model of Nakamura (1983) (N83) used travel times from a total of 81 events, and it specified four crustal layers, with mantle interfaces at 270 and 500 km depth. The model minimized the root-mean-square misfit of the predicted and observed travel times, linearizing about the starting model. Nakamura (1983) stressed that the choice of interface depths and the specification of constant velocity layers was arbitrary. P- and S-wave travel times were repicked for 59 events by Lognonné et al. (2003) and used in models by Lognonné et al. (2003) and Gagnepain-Beyneix et al. (2006) (L03 and GB06, respectively) that specify three to four mantle layers and four to six crustal layers. The Khan et al. (2007) model used a Monte Carlo simulation approach, combined with Bayesian inference, to find families of compositional, density, and thermal models compatible with the L03 travel-time data set

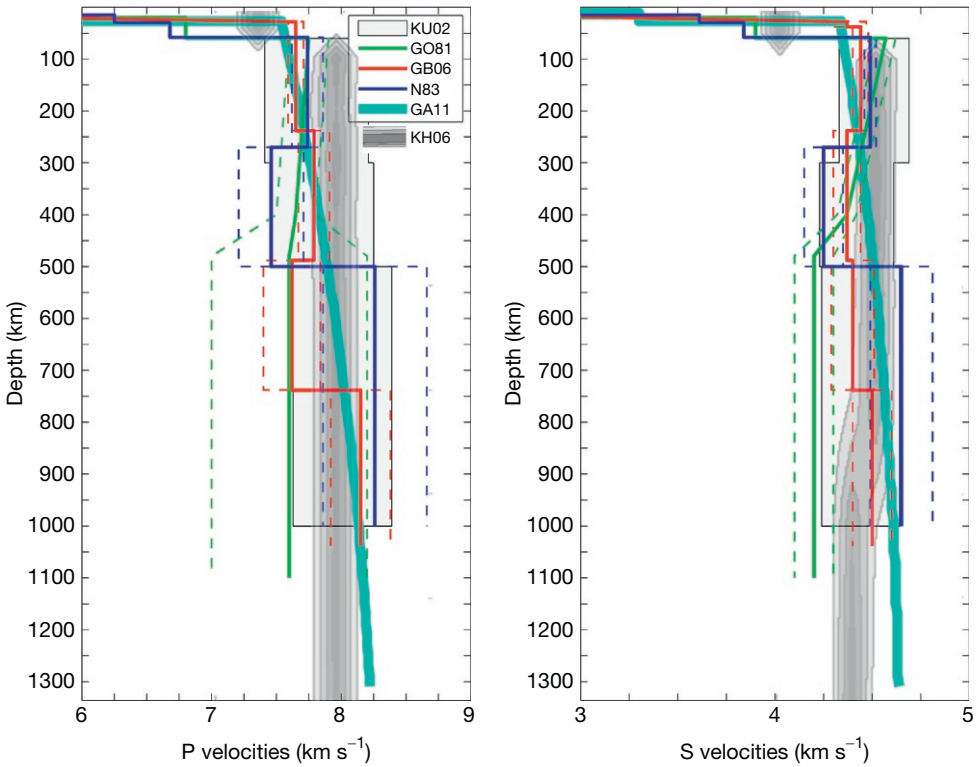

Figure 5 P- and S-wave velocity models versus depth: green – Goins et al. (1981b) (G081), red – Gagnepain-Beyneix et al. (2006) (GB06), dark blue – Nakamura (1983) (N83), light blue – Garcia et al. (2011) (GA11). From light to dark, the gray zones are the zones of increasing probability from Khan et al. (2006) (KH06). The light gray represents the petrology–geochemistry model of Kuskov et al. (2002) (KU02). Values for mantle velocities and associated 1σ uncertainties for each model can be found in Table 1 of Lognonné (2005) and are plotted using dashed lines for the three first models.

and the lunar mass and moment of inertia. A similar inversion approach was used by Kuskov et al. (2002), but only the lunar mass and moment of inertia were inverted, and thus, the resulting seismic-velocity models could be compared in a predictive sense with those independently derived from the travel-time data. The most recent, comprehensive lunar seismic-velocity model is the model created by Garcia et al. (2011) (GA11). This study uses the travel-time data set of L03. GA11 takes the crustal velocity structure from GB06 and constructs a series of mantle velocity models for different core radii. For each core radius, core densities are computed that match the mass, moment of inertia, and Love numbers. GA11 then uses horizontally polarized, reflected S waves, combined with previously published attenuation parameters (Nakamura and Koyama, 1982; Nakamura et al., 1982), to establish the preferred core radius (see also **Section 10.03.2.3**) and, hence, the preferred overlying mantle-velocity model.

Crustal structure is primarily controlled by impacts. Seismic ray theory predicts that near-receiver impacts (mostly the artificial impacts) will have rays that turn within the crust. In addition, distant impacts produce seismic energy that travels through the crust near the source location, and then again near the receiver location. Thus, in theory, the travel times of P and S waves should constrain crustal thickness and velocity structure, with the strongest constraints near the longest-lived Apollo stations (12 and 14). Additional data for investigating crustal structure come from observations of S-to-P converted phases (Vinnik et al., 2001), the data for which have been recorded at stations A12 and A16 (at A14 and A15, data were either missing or too noisy). Converted phases were only detected at the Apollo 12 station and originated from a seismic-velocity discontinuity interpreted as the crust–mantle boundary. The terrestrial seismological literature refers to such studies as receiver function studies. The combination of the differential travel time and the relative amplitude of the primary and converted phases provides information on the depth of and the impedance contrast across the discontinuity. However, the lunar data set is less than ideal. More recent studies use 17 (L03) or 14 (GB06) travel times from 8 (L03) or 7 (GB03) artificial impacts and 88 travel times from 19 natural impacts. As the latter require estimates of three (latitude, longitude, and source time) source parameters, the total number of degrees of freedom is reduced to 48 (L03) or 45 (GB06). Travel times and relative amplitudes for converted phases from only one receiver location are sufficiently reliable for incorporation into velocity-profile modeling (L03, GB06).

Figure 5 shows the significant variability among crustal velocity models, particularly regarding crustal thickness. By analogy with Earth, the lunar seismological crust-mantle interface is defined by a velocity discontinuity or steep gradient (>0.1 km s^{-1} km^{-1}), below which the P-wave velocity should attain a value of at least 7.6 km s^{-1}. Specifically, depending on the model, crustal thickness is estimated to be 58 km (Goins et al., 1981b; *N83*, and see also earlier work by Toksöz, 1974), ~38–45 km (Khan and Mosegaard, 2002; KM07; Khan et al., 2000), and 30 km (GB06) (Figure 5). The velocity structure at depths of 30–60 km is quite sensitive to a few travel-time data (see discussion in GB06). Figure 6 shows the sampling of the lunar interior by way of ray paths connecting the events and receivers shown in Figure 4.

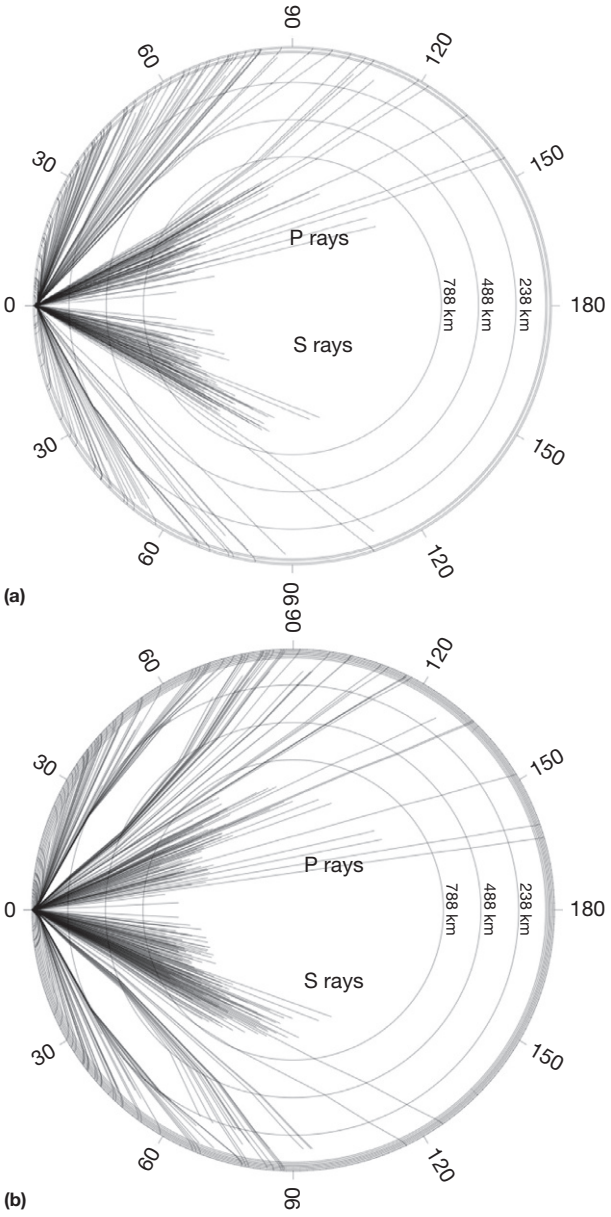

Figure 6 Summary of the source–receiver seismic ray paths for two different seismic models of the Moon. The top model (a) is determined using the travel times of Gagnepain-Beyneix et al. (2006), and the bottom model (b) is determined using the travel times of Nakamura (1983). Rays are plotted with the stations all located at 0° and the source at the actual depth and epicentral distance from the station. Note the rays associated with deep moonquakes. The crustal thickness in (a) is 30 km, below which there is a 10-km transition zone with a shear wave gradient. The crustal thickness for model (b) is 58 km. Despite differences in mantle sampling, no rays sound the lunar core for both models. Reprinted from Gagnepain-Beyneix J, Lognonné P, Chenet H, and Spohn T (2006) Seismic models of the moon and their constraints on the mantle temperature and mineralogy. *Physics of the Earth and Planetary Interiors* 159: 140–166, with permission from Physics of the Earth and Planetary Interior.

The ray path coverage is uneven with changes in depth, and, while hard to see in Figure 6, the sampling of very shallow depths (<60 km) is poor. While uncertainties in crustal

thickness remain, four main conclusions can be drawn from the seismological data. First, although the profiles shown in Figure 5 are 1D velocity profiles, the source–receiver geometries and ray theory indicate that the averaged crustal thickness primarily reflects the crustal structure at the Apollo 12 and 14 sites. Second, several recent tests indicate that the crust at the Apollo 12/14 sites is more likely to have a thickness of 30–45 km (KM02, L03, GB06), rather than the ~60-km thickness previously estimated (N83). Third, although not discussed here, an attempt has been made to investigate geographical variations in crustal thickness, using the Apollo seismic data (Chenet et al., 2006). While only a few estimates are possible, they show a high level of agreement with relative crustal thickness variations deduced from gravity and topography data prior to the GRAIL mission. Finally, high-resolution gravity and topography data from the GRAIL (Zuber et al., 2013) and Lunar Reconnaissance Orbiter missions have shown that the bulk density of the lunar highlands is 2550 kg m^{-3}, which is much lower than typically assumed (Wieczorek et al., 2013), but the new data also produces estimates of crustal thickness similar to the seismically derived crustal thicknesses of 30 km (L03, GB06) to 38 km (Khan and Mosegaard, 2002).

Estimates of seismic-velocity structure within the crust are variable (Figure 5). While literature has addressed the range of estimates, the variability among models mainly reflects the limited data set. Perhaps the most satisfactory summary of the seismic data asserts that the recorded seismic activity is broadly consistent with a crustal structure in which there are two major compositional layers – an upper anorthositic (lower seismic velocity) and lower noritic (higher seismic velocity) crust – consistent with inferences from gravity and topography data (Wieczorek et al., 2006). Seismologically, higher velocities are associated with the noritic lower crust. Some suggestions of a midcrustal reflector have been made (e.g., the 20-km discontinuity of Khan and Mosegaard, 2002). Furthermore, as discussed in Section 10.03.2.1, the megaregolith likely results in scattering of seismic energy and, thus, significantly reduced seismic velocities in the upper ~1 km (GB06 and see review in Wieczorek et al., 2006). This scattering is supported by the high average crustal porosities inferred from GRAIL (Wieczorek et al., 2013), and, in fact, a layer with v_p ~1 km s^{-1} may extend to over 3 km in depth, at least beneath the Apollo 17 site (Nakamura, 2011). This high near-surface porosity contributed to (and can explain) earlier thicker estimates of the lunar crustal thickness.

Despite the variability in the shallow structure, upper mantle (<300 km) velocity estimates are generally in agreement at around 7.7 km s^{-1} for P waves and 4.5 km s^{-1} for S waves (L03, N83, GB06). Velocity estimates in the 270–1000-km region are constrained primarily by travel-time picks from deep events. A midmantle (300–500 km depth) low-velocity zone or negative velocity gradient was suggested by N83, and this low-velocity zone is permitted, although not required (Figures 5–7 and following discussion). In particular, the crustal structure of N83 results in very poor ray coverage of the depth region from 300 to 500 km (Figure 6). The trade-off is that improved coverage of this region can be obtained (e.g., with thinner crustal thicknesses) at the expense of poor coverage at 500–800 km of depth (Figure 6, and see the discussion in GB06). The smoothly varying P- and S-wave mantle-velocity profiles of G11 lie between all previously proposed 1D models. Seismic velocities below ~1000 km are essentially unconstrained (Figure 6), although the absence of moonquakes below this depth may be consistent with possible high shear-wave attenuation, the latter having been proposed to explain the lack of shear-wave arrivals from the few detected far-side deep moonquakes (Nakamura et al., 1973). Inversions of the seismic data for a lunar-temperature profile (Gagnepain-Beyneix et al., 2006) suggest temperatures of about 1200 °C at this depth. All these observations argue for a warmer, more ductile lower mantle.

The effect on seismic-velocity-model resolution of ray-path coverage is also illustrated by a sensitivity analysis of GB06. We examine the sensitivity of the travel-time data set to perturbations to GB06. Weighted root mean square (RMS) misfits are calculated for velocity models in which the velocity is as specified in GB06, except in one depth interval. In this depth interval, the velocity is either increased (red line, Figure 7) or decreased (blue line, Figure 7) by 10% relative to the published value. Depth intervals are 100 km thick, except where the published model comprises a thinner layer. In the case of a thinner layer, the published layer thickness is used. The RMS misfit between the travel times predicted by GB06 (Figure 5) and the measured travel times is ~5.9 s, which is comparable to the RMS of the errors assigned to the data (~6.2 s). We instead show a weighted RMS misfit (Figure 7) for which each travel-time residual (observed minus predicted) is divided by the uncertainty in the travel-time pick (1, 3, or 10 s, see Lognonné et al., 2003), and the total RMS is further normalized such that GB06 fits the data to a weighted RMS of 1.0.

We then investigate perturbations to the P-wave and S-wave velocity models, calculating the RMS misfit using only the P- or S-wave arrival times, respectively (Figure 7(b) and 7(c)). In each of these cases, the v_p/v_s ratio can vary relative to the ratio specified in GB06. The travel-time data are more sensitive to perturbations in v_s than to perturbations in v_p, with the corresponding RMS misfits showing greater variation (Figure 7(c)). Models with a v_p/v_s ratio lower than the ratio from GB06 (higher v_s, Figure 7(c), or lower v_p, Figure 7(b)) are acceptable when compared with GB06, however, and models with lower ratios can even result in an improved misfit to the data set. (The exception is the depth interval 1000–1100 km, which contains the source depths of some deep moonquakes.) This may seem surprising at first, but one should remember that the analysis of GB06 is an inverse approach with a priori constraints applied. In other words, the best-fit model is determined according to some a priori criteria not applied here. Models with higher v_p/v_s ratios (i.e., increased v_p or decreased v_s) have larger RMS misfits than GB06, and with the exception of the perturbations to v_p in the depth range 500–800 km, these models result in more than a 10% RMS misfit increase, with the increase being as high as 50% for −10% perturbations to v_s in the depth range 100–200 km.

Somewhat different results are obtained if v_s and v_p are both allowed to vary, holding the v_p/v_s ratio constant. At depths shallower than 200 km, the travel-time observations allow for discrimination between plausible models. In particular, decreases in seismic velocity at depths <200 km generate increases in misfit levels of more than 30%. At depths of 300–500 km, there is some sensitivity to seismic structure,

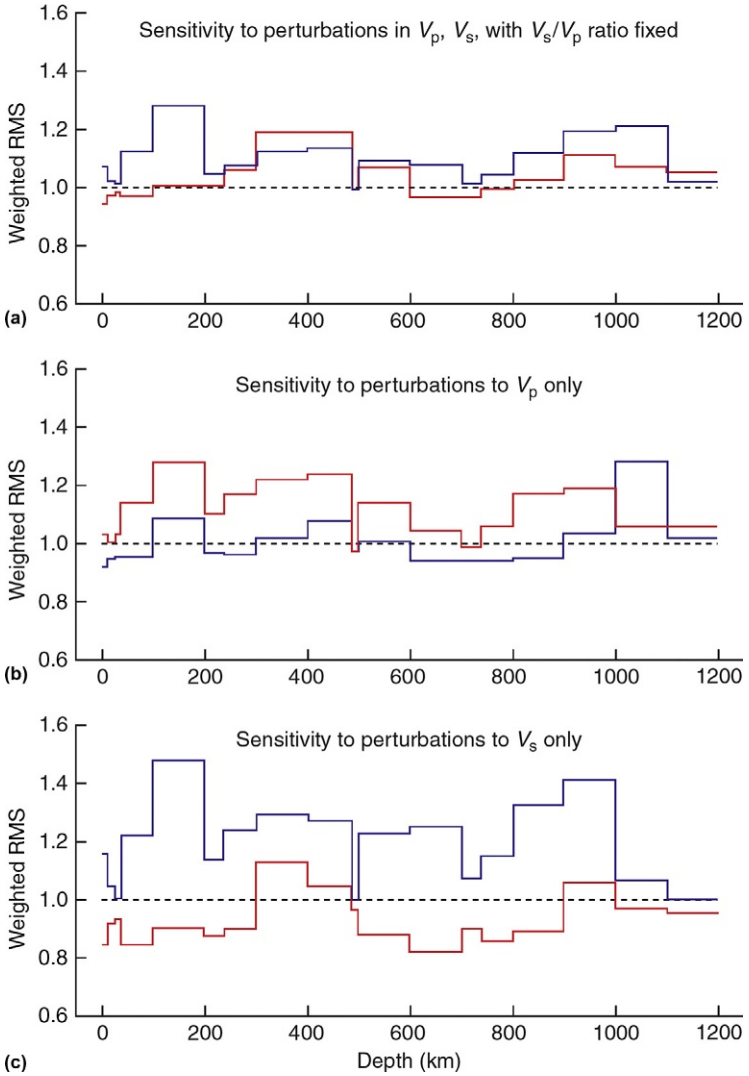

Figure 7 Weighted RMS misfit of the predicted travel times to the observed travel times (Lognonné et al., 2003) for velocity models in which GB06 is perturbed by 10% in a specified 100-km-thick interval. Where the published velocity model comprises layers of thickness <100 km, the published layer thickness is used. Travel-time residuals (observed minus predicted) are weighted by the uncertainty in the travel-time pick, and the total misfit is normalized such that the misfit to the unperturbed GB06 is 1 (dashed line). Red – GB06 increased by 10% as a function of depth (red); blue – GB06 decreased by 10%. (a) The v_p/v_s ratio is held constant, as specified in GB06, the P-wave velocity is perturbed by $\pm 10\%$ in a specified depth interval, and v_s is perturbed using the v_s ratio. RMS misfit is computed using both P and S arrival times. (b) Only v_p is perturbed by $\pm 10\%$, and the misfit to the P-wave arrival times computed. (c) Only v_s is perturbed by $\pm 10\%$, and the misfit to the S-wave arrival times computed.

and models with 10% increases or decreases in velocity provide poorer fits to the data. Sensitivity at depths of 500–800 km is more limited, however, and, in particular, higher velocities can be tolerated with little change in RMS misfit. Sensitivity in the region of deep moonquakes again increases, with lower velocities resulting in a poorer fit to the data.

In summary, the lunar seismic events recorded by the Apollo network have resulted in travel-time data sets (Lognonné et al., 2003; Nakamura, 1983) that enabled 1D seismic-velocity profiles to be inferred to depths of about 1200 km. Recent work suggests a revision of crustal thickness from previous estimates of ~60 km (Nakamura, 1983) (an average value, probably most representative of the thickness in the Apollo station 12 and 14 region) to <45 km (Khan et al., 2000). The lower thickness value could be around 38 km, as proposed by Khan and Mosegaard (2002), or it could be as low as 30 km (Gagnepain-Beyneix et al., 2006; Lognonné et al., 2003). While both models are compatible with the receiver-function arrival times (Vinnik et al., 2001), models of receiver-function amplitudes favor a thin crust with low seismic velocities. Upper mantle seismic-velocity estimates are generally in agreement. Sensitivity to seismic velocity in the midmantle (300–700 km) is limited and critically depends on the crustal structure. Thus, a range of models is permitted, including those with small-amplitude negative seismic-velocity discontinuities or gradients at ~300 km depth and those with sharp positive discontinuities at ~500 km depth (**Figures 6** and **7**). Seismic-velocity estimates in the deep-moonquake zone differ, with P-wave velocities as high as 10 km s^{-1} obtained as a result of some travel-time data inversions

(Khan and Mosegaard, 2002; Khan et al., 2000), and all models show velocities higher than those in the upper mantle.

In **Section 10.03.2.4,** we summarize the constraints that the seismic models place on lunar thermal and mineralogical structures. Much of the remaining disagreement among 1D velocity models likely results from errors in arrival-time determinations, lack of resolution, differences in inversion techniques, and averaging of 3D structure. Despite initial attempts to use 3D tomography to determine mantle (Zhao et al., 2008, 2012) and crustal thickness (Chenet et al., 2006), and even with more rigorous modeling techniques (e.g., Wang et al., 2013a,b), four stations provide very limited 3D tomography with nonlocated sources. Thus, the next generation of 3D models will depend on constraining the location of the largest meteorite impacts by identifying of the freshest crater with LRO (Lunar Reconnaissance Orbiter) data. The low resolution of the Apollo seismometers and their limited bandwidth may also lead to a misinterpretation of the P and S arrival times, if the first arrivals are too small to be detected, as illustrated by Nakamura (2005), who studied the deviation between five arrival-time data sets (Goins, 1977; Lammlein, 1977; Lognonné et al., 2003; Nakamura, 1983, 2005). Differences between these data sets are large – often 10 s or more – and illustrate the difficulties of phase-picking in narrow band records of scattered waves. KM02, GB06, and N83 also employ differing inversion procedures, especially with regards to the relocalization procedure performed after each iteration. In view of the combined effects of 3D structure and poor seismic sampling of the lunar interior due to the limited source–receiver geometries, new data provided by future networks with very-broad-band (VBB) seismometers are required. Therefore, several projects in Japan (e.g., SELENE2, Tanaka et al., 2013), the United States (e.g., Lunette, Neal et al., 2011), and Europe (e.g., FARSIDE, Mimoun et al., 2012) have been proposed for establishing a new seismic station(s) on the Moon.

10.03.2.3 Very Deep Interior

Many geophysical studies indicate that the Moon has a core (for a review see Hood and Zuber, 2000), which is evidenced by magnetic induction signatures (Hood et al., 1999) or remanent magnetism (Hood, 1995; reviewed in Cisowski et al., 1983; Fuller and Stanley, 1987). Geochemical analyses of mare basalt samples indicate a depletion of highly siderophile elements (e.g., Righter, 2002) relative to the depletion level expected from any lunar-core formation scenario (Canup and Asphaug, 2001). Impact simulations (see Cameron, 2000) suggest that a low fraction of iron from the proto-Earth and proto-Moon was put into orbit after the giant impact. These mass-fraction estimates are typically 1% or less, and they reach 3% in only a few extreme cases, as iron can be further added during late-stage accretion.

Until recently, the only methods for directly investigating the lunar core were magnetic sounding and geodesy. Magnetic sounding (Hood et al., 1999) is based on the induced magnetic dipole moment produced by the motion of the Moon through the Earth's geomagnetic tail. A core radius of 340 ± 90 km is inferred by this method, under the assumption that electric currents in the core can be approximated by a current 'sheet' localized on the core surface. The second approach, the measurement of the moment of inertia ratio (0.3932 ± 0.0002, Konopliv et al., 1998), indicates that the density toward the center of the Moon is higher than it is inside the lunar mantle. Moreover, analyses of lunar rotation (Bois et al., 1996; Williams et al., 2001) have shown that the rotation of the Moon is influenced by a dissipation source, which has been interpreted as the signature of a liquid core.

A lunar core was also suggested by interior structure models obtained from inversions of the density, moment of inertia, Love number (k_2), and even the induction signature, with or without the additional constraints provided by the seismic data. Bills and Rubincam (1995) used the mean density and the inertia factor only and they estimated a core radius of 400 and 600 km, respectively, for densities of 8000 and 6000 kg m^{-3}. Khan et al. (2004) used these constraints, along with the Love number, and performed a Monte Carlo inversion assuming a 5-shell model. The inversion inferred a core with a radius of about 350 km and a density of 7200 kg m^{-3}. As several tradeoffs exist between the size and density of these layers, the independent constraints from seismology can be added in order to limit the space of acceptable models. Interior structure inversions based on a priori seismic models were first performed by Bills and Ferrari (1977), using a preliminary seismic model, and later by Kuskov and Kronrod (1998) and Kuskov et al. (2002), using Nakamura's (1983) seismic model. Kuskov and colleagues proposed either a pure γ-Fe core with a density of 8100 kg m^{-3} and a radius of 350 km or a core with smaller densities and larger radius, including the largest troilite FeS core with a radius of 530 km and a density of 4700 kg m^{-3}. Khan et al. (2006) performed another study using seismic information, the inertia factor, and the mean density, and he predicted a core with a density of about 5500 kg m^{-3}.

The geometry of the lunar network, particularly, its lack of any antipodal stations mean that the system has recorded few, if any, ray paths propagating deep in the Moon (>1200 km depth) (**Figure 6**; see Nakamura et al., 1974b for an impact on the far side). Therefore, the body's core cannot be geometrically determined by direct waves (e.g., Knapmeyer, 2011). An alternative approach for investigating core structure involves exploring a planet's normal modes (e.g., Lognonné and Clévédé, 2002). A search for free oscillations in the Apollo data has been performed by a few authors, as low-angular-order normal modes are sensitive to core structure. After an unsuccessful attempt by Loudin and Alexander (1978), Khan and Mosegaard (2001) claimed detection of free oscillations from flat-mode LP Apollo signals generated by meteorite impacts. However, Lognonné (2005) and Gagnepain-Beyneix et al. (2006) have shown that the signal-to-noise ratio of these events was probably too small to result in detectable LP signatures. Nakamura (2005) has suggested the presence of about 30 possible deep moonquake source regions on the lunar farside: however, no events were detected within 40° of the antipode of the mean sub-Earth point, suggesting that this region is either aseismic or strongly attenuates or deflects seismic energy (Nakamura, 2005; Nakamura et al., 1982).

Two recent studies have independently reanalyzed Apollo seismograms using modern waveform methods to search for reflected and converted seismic energy from a lunar core, by using stacking methods. The success of these two analyses can

be understood through Figure 8(a), which shows the amplitudes of the individual deep-moonquake P and S waves, on which the typical amplitudes of core phases have been superimposed (for simple isotropic sources). This illustrates the relatively low amplitude of the ScS phases with respect to the instrument detection threshold and suggests the possibility of signal enhancement by stacking. These stacks form the basis for the search performed by the two separate studies of Weber et al. (2011) and Garcia et al. (2011).

Weber et al. (2011) used polarization filtering (similar to the double-beam stacking method in terrestrial array seismology) to attempt to identify reflected core phases (PcP, ScS, ScP, and PcS) from three deep lunar interfaces: the top of a partial-melt layer at the base of the mantle, the interface between an outer fluid core and the lower mantle partial-melt layer, and the interface between an inner solid and outer fluid core. P- and S-wave velocities in the layers, as well as the radius of the interfaces, were determined. The resulting model is one in which the top of the partial-melt layer lies at a radius of 480 ± 15 km, and the tops of the outer and inner core are at 330 ± 20 and 240 ± 10 km, respectively. The inferred solid- and liquid-core radii suggest a core that is 60% liquid by volume, and these measurements constrain the concentration of light elements in the outer core at less than 6 wt%. Garcia et al. (2011) constructed a 1D reference Moon model incorporating both seismological and geodetic (density, moment of inertia, and Love number (k_2)) constraints. First, radial variations in P- and S-wave velocities and density that match the seismic and geodetic data were inverted for different values of core radius. Then, using waveform stacking and a polarization filtering technique, but also taking into account a correction for the gain of the horizontal sensors, a best-fit core radius was determined. Garcia et al. (2011) found a best-fit core radius of 380 ± 40 km, larger than the radius determined by Weber et al. (2011), thus permitting somewhat higher concentrations of light elements (up to 10 wt%) and a best-fit mean core density of 5200 ± 1000 kg m^{-3}, which is significantly different from the average density of the inner and outer core of 6215 kg m^{-3} found by Weber et al. (2011).

These two seismic analyses confirm the existence of the core, and both support a fluid outer core and a solid inner core. However, the uncertainties in core radius remain large, with estimates ranging from 300 to 400 km, and, in fact, most of the deep geophysical properties of the Moon are still weakly constrained. Figure 8(b) shows the typical range of several deep lunar parameters, such as mid- and lower-mantle density, lower-mantle shear-wave velocity, core radius, and core density. The inverse problem remains underdetermined (the data are k_2 Love number, density, moment of inertia factor, and the ScS travel time). The two seismic models of Weber et al. (2011) and Garcia et al. (2011) mainly differ in their treatment of the lower mantle structure. This structure is proposed to be a low-velocity, partially melted zone by Weber et al. (2011), in contrast to the model of Garcia et al. (2011), in which this zone has velocities close to those in the midmantle. These data and models all suggest a core that comprises 0.75–1.75% of the lunar mass with a mean density less than 6215 kg m^{-3}, consistent with the presence of some light element(s). This is also consistent with estimates of the temperature at the core–mantle boundary, which are compatible with a liquid core only if the latter contains light elements (Gagnepain-Beyneix et al., 2006; Khan et al., 2006; Lognonné et al., 2003). A core with little or no light elements, corresponding to the high densities found by Khan et al. (2004), will likely be solid at those temperatures and can be excluded.

More precise deep-interior-structure estimation will depend on new geophysical data and (even independent of these) on better estimation of the thermal state of the lunar lower mantle. Such constraints might possibly be obtained from deep-moonquake dynamics, as they provide another important constraint on deep lunar structure. Density and elastic moduli from the seismic models can indeed be used to explore tidal stresses as a function of depth (Figure 9) and/or time (Bulow et al., 2006). Understanding tidal stresses as a function of time and position is critical to understanding how and why deep moonquakes occur, because the seismic data distribution and quality prohibit the inference of focal mechanisms for these events.

10.03.2.4 Mineralogical and Thermal Interpretation of Lunar Seismic Models

Considerable effort has been expended in interpreting the depth dependence of lunar seismic velocity in terms of mineralogical and thermal structure. An excellent review of this topic has been given recently by Wieczorek et al. (2006), and so we focus here on only the major results and outstanding issues from these studies. Two general approaches have been used: investigations of a limited suite of compositional/mantle mineral assemblages (e.g., Gagnepain-Beyneix et al., 2006; Hood and Jones, 1987; Lognonné et al., 2003; Mueller et al., 1988), and a more complete thermodynamic treatment (series of papers by Kuskov and colleagues, e.g., Johnson et al., 2005; Khan et al., 2006, 2007; Kuskov, 1995, 1997; Kuskov and Fabrichanaya, 1994; Kuskov and Kronrod, 1998, 2009; Kuskov et al., 2002). In the latter approach, a bulk composition is specified as a function of depth, and the equilibrium mineralogical assemblage is calculated for a given selenotherm (lunar temperature profile), from which the elastic moduli and resulting seismic velocities can be predicted. An example is the model of Kuskov et al. (2002) in Figure 5. Seismic velocity models predicted from mineralogy can then be compared with those inferred from travel-time data, and the mass and moment of inertia can be compared with geodetic constraints. Alternatively, travel times can be calculated using the predicted seismic-velocity models and compared directly with the observations (Johnson et al., 2005; Khan et al., 2006, 2007). Of particular interest for the Moon have been (i) the bounds that crustal thickness (through the concentration of heat-producing elements in the crust) and mantle seismic velocities place on temperature, (ii) whether mantle seismic velocities can discriminate among broad classes of interior differentiation models, and (iii) whether phase changes are identifiable in the seismic velocity structure.

Studies to date (Hood and Jones, 1987; Khan et al., 2006; Mueller et al., 1988) show that no single compositional model predicts seismic velocities that match both the upper and lower mantle 1D profiles, even when temperature and pressure effects are accounted for. In general, models that assume

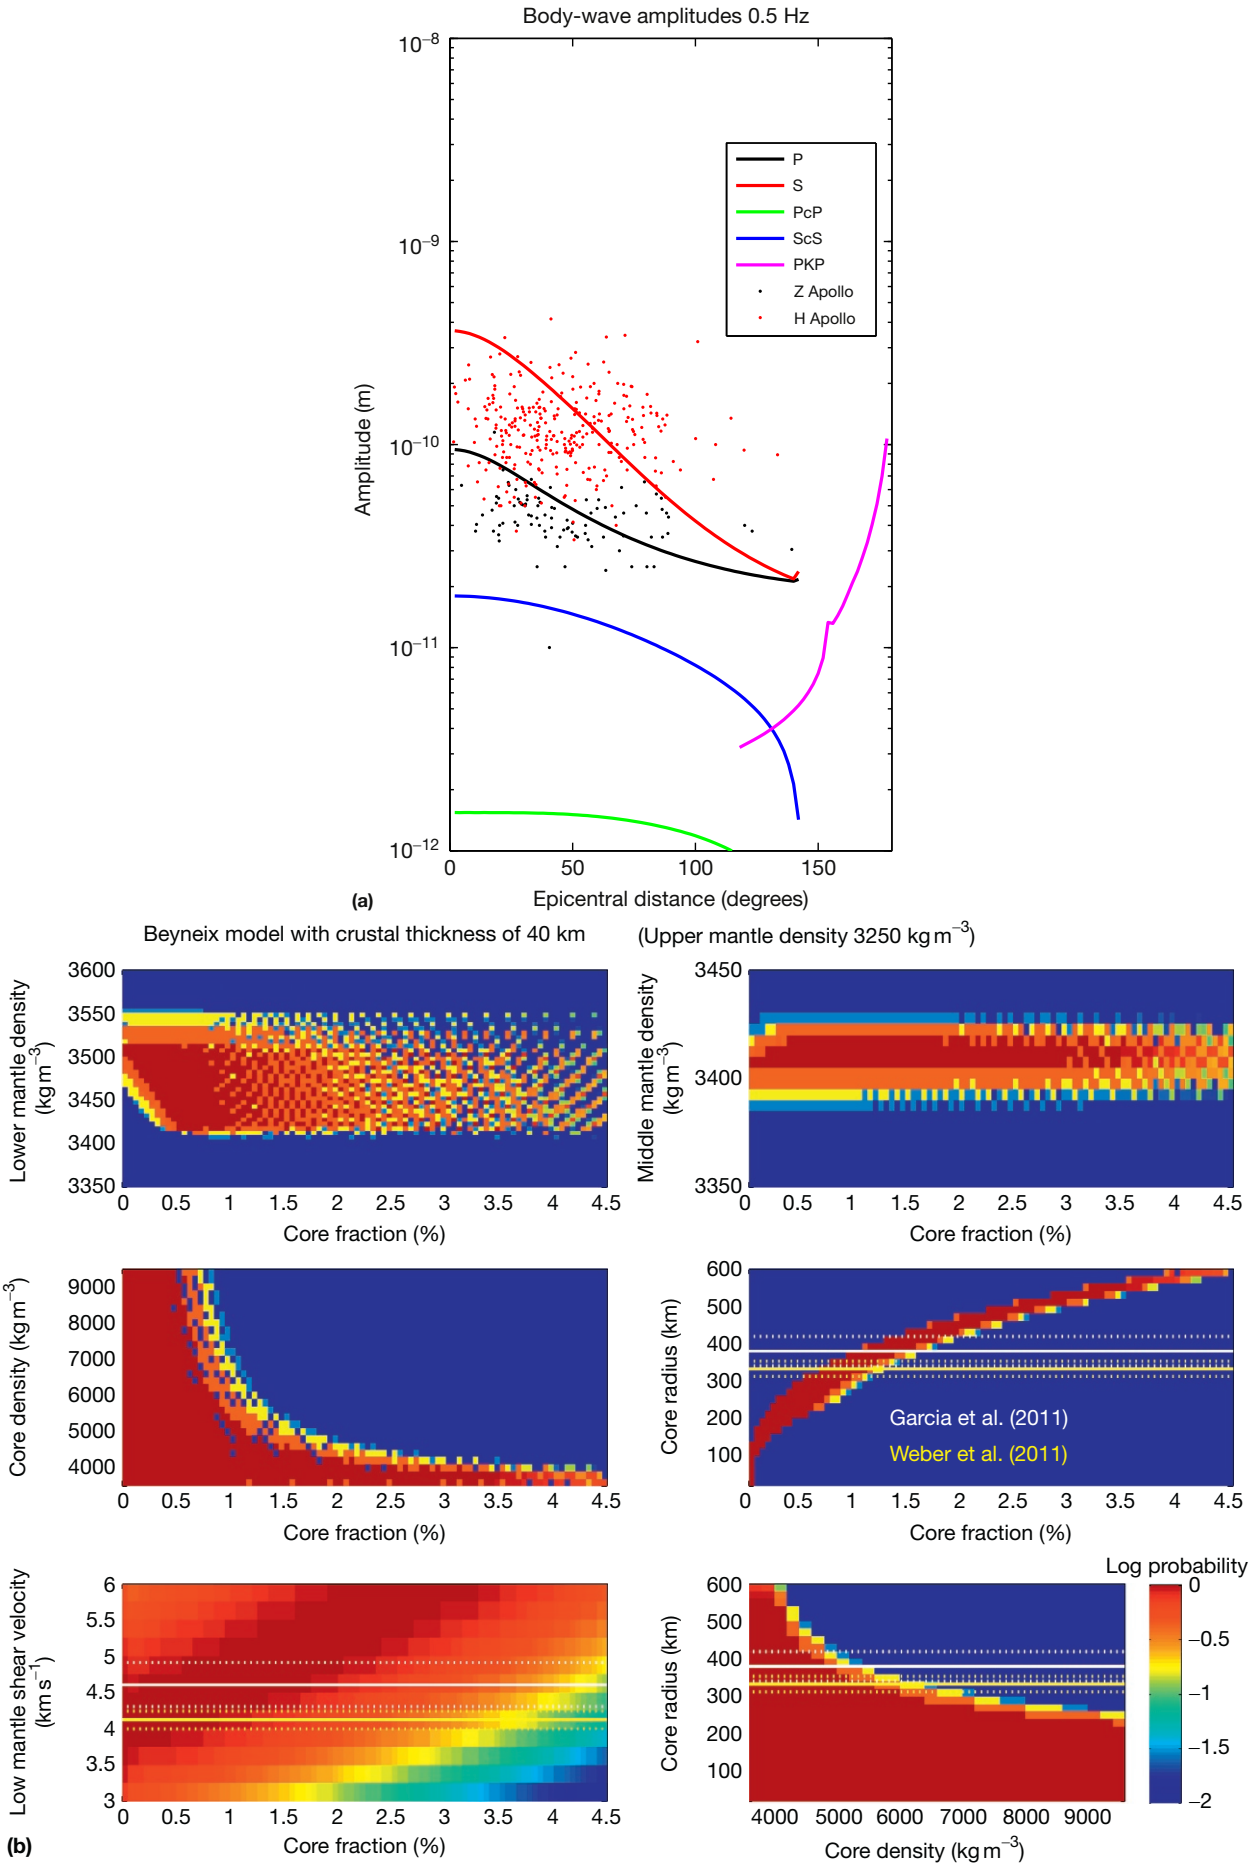

Figure 8 (Continued)

differentiation of the upper mantle and that are more aluminous in bulk composition than the terrestrial mantle are favored. As most mineralogical studies compared their predicted seismic velocities with the Nakamura (1983) model, a focal point was the presence or absence in the predictions of a velocity discontinuity at 500 km. Both phase changes (Hood and Jones, 1987; Mueller et al., 1988) and compositional boundaries (Kuskov, 1997; Mueller et al., 1988) at this depth were inferred. Compositional boundaries were of interest as they may reflect the initial compositional zoning of the Moon, its basis in an early lunar magma ocean, its resulting crystallization sequence, and the maximum melting depth of the mare basalt region (see discussion in Wieczorek et al., 2006). The discussion in **Section 10.03.2.2** indicates that the arrival times

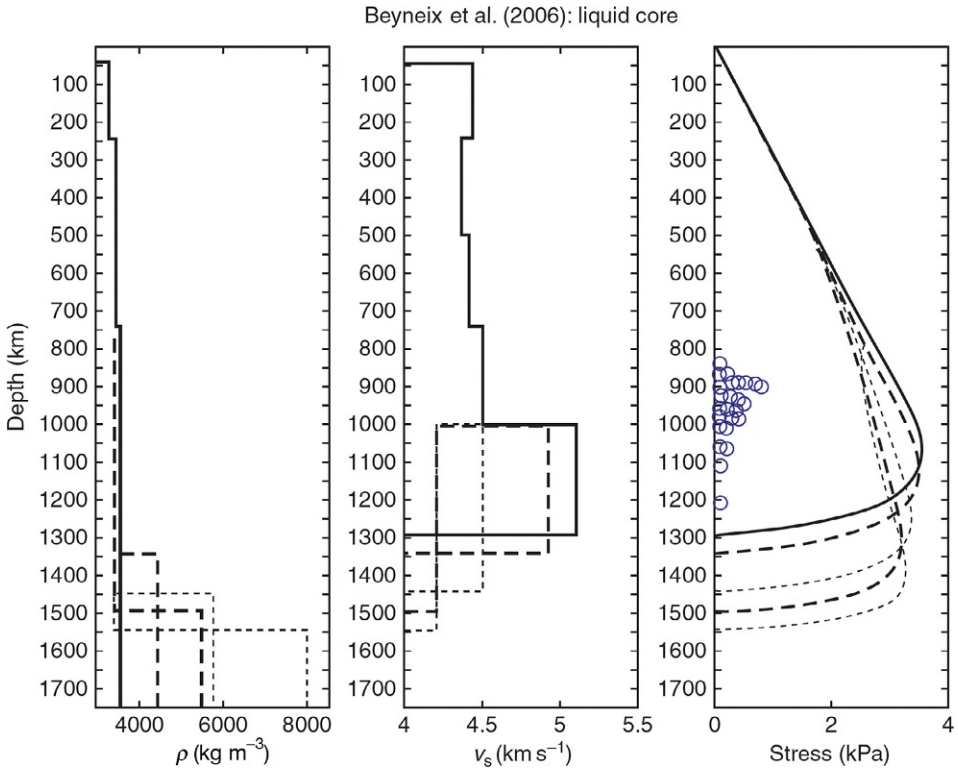

Figure 9 More specific illustration of the trade-off between lower-mantle rigidity and core radius. All seismic and density models shown match the Apollo seismic travel times, the mean density, moment inertia, and k_2 within the data error bars. All models have S-wave velocity values calculated by Gagnepain-Beyneix et al. (2006) for the mantle and crust, and only the shear velocity in the very deep mantle is modified. Shear velocity in the core is zero, as only models with liquid cores are shown. The various lines are each associated with a given core size and minimize the variance. From left to right, the figures represent the density, the shear-wave velocity, and the tidal stresses. Models with the largest cores (400 km or more) correspond to an ilmenite core with densities lower than 5000 kg m^{-3}. These models have correspondingly high shear velocity in the lower mantle. Models with a core radius of 350 km correspond to an FeS core, with densities in the range of 5000–6000 kg m^{-3}. Smaller cores (~200 km) of larger densities are also compatible with the data, if associated with a low-velocity zone in the lower mantle, in order to match the low k_2 value. On the far right, the maximum horizontal tidal stress is shown with respect to the depth and defined as $(T_{\theta\theta}+T_{\phi\phi})/2$, where T is the tidal stress tensor, at the latitude and longitude of the deep Moonquake A1 (as found by Gagnepain-Beyneix et al. (2006), i.e., -15.27° S, -34.04° E). See Minshull and Goulty (1988) for more details on stress computations. Note that only models with a core radius of 350 km or more produce maximum tidal stresses in the vicinity of the deep moonquakes.

Figure 8 (a) Typical amplitudes of the P and S body waves of deep moonquakes detected by Apollo, as a function of epicentral distance. Z Apollo are the amplitudes recorded for P on the vertical axis of Apollo, while H Apollo are those for S on the horizontal axis. The amplitudes are taken from the Nakamura et al. (2008) catalog, but converted to displacement using conversion factors between mm and peak-to-zero displacement obtained through the comparison of the catalog amplitudes with amplitudes recorded by the A1 deep-moonquake seismograms after instrument correction. As an indication, typical relative amplitudes of P, S, and core phases (ScS, PcP, and PKP) are plotted for the interior model of Garcia et al. (2011), illustrating that ScS amplitudes, although too small to be individually detected in the Apollo data, might be detected through stacking for the largest events. PcP phases have amplitudes that are too small to be identified with stacking, however, and they will remain challenging, even for the next generation of lunar seismometers. (b) Exploration of the model space for acceptable models for density, inertia factor, and Love number k_2, using the seismic models of Gagnepain-Beyneix et al. (2006), compared to the core estimations of Garcia et al. (2011) and Weber et al. (2011), which are represented by white and yellow lines, respectively. The middle mantle is defined as occurring between 1500 and 1000 km radius, while the lower mantle occurs between 1000 km and the core radius. The color scale represents the decimal logarithm of exp(−var), proportional to the probability, where the variance is between the computed and observed densities, moment of inertia, and k_2. For the variance definition, values, and errors, see Khan et al. (2004). Acceptable models are dark red and red. The model space is sampled in order to identify the range of acceptable solutions. In the middle–lower mantle S-wave velocities are equal to 4.5 km s^{-1} in the models of Gagnepain-Beyneix et al. (2006), while the mean velocities of Garcia et al. (2011) and Weber et al. (2011) are 4.6 and 4.125 km s^{-1}, respectively.

show limited sensitivity to velocity structure at depths of 300–500 km, and even up to 800 km, and the section cautions against overinterpretation of mantle structure in this region. Overall, however, the increase in seismic velocity from the uppermost mantle (0–300 km) to the region of deep moonquakes (700–1200 km) is consistent with a change in bulk composition from a dominantly orthopyroxene upper mantle (with lesser amounts of olivine, clinopyroxene, plagioclase, and garnet) to a dominantly olivine lower mantle (with smaller amounts of garnet and clinopyroxene) (Wieczorek et al., 2006). This kind of compositional change is associated with an increase in magnesium number with depth. The studies by Lognonné et al. (2003), Gagnepain-Beyneix et al. (2006), and Khan et al. (2006) demonstrate the broad range of acceptable models, given current seismic constraints.

Crustal thickness plays an important role in determining the thermal profile of the lunar interior due to the preferential sequestration of heat-producing elements in the crust. Again, a large range of thermal profiles and resulting mineralogical assemblages are compatible with the seismic data (Khan et al., 2006), but recent studies indicate a preference for 'cold' thermal profiles (Gagnepain-Beyneix et al., 2006; Lognonné et al., 2003), with a temperature of 1073 K at 340-km deep (equivalent to the base of the terrestrial elastic lithosphere) and a temperature of 1473 K at 740-km deep (base of terrestrial thermal lithosphere). Such depths are comparable to the depths found in thermal evolution models of the Moon (e.g., Spohn et al., 2001a). In these models, bulk lunar abundances of the heat-producing elements uranium and thorium are similar to terrestrial values, with an enriched crust and a depleted mantle. For example, mantle abundances of about 8.2 ppb of U and 30 ppb of Th are suggested by Gagnepain-Beyneix et al. (2006) in order to fit the temperature dependence of seismic velocity. These values of U and Th abundances are close to those proposed by Waenke et al. (1977) and Taylor (1982).

Taken together, mineralogical and thermal studies of the lunar interior, using seismic data, show that a broad range of interior models are compatible with that data. Yet, the existing models still have limitations, including a lack of detail regarding thermodynamic parameterization and the absence of titanium (and sometimes sodium) from calculations. Furthermore, the likelihood of 3D structure in the Moon is great, as suggested by petrological models (e.g., Elkins-Tanton et al., 2011), the possible spatial association of deep moonquakes with the lunar mare (Qin et al., 2012; Watters and Johnson, 2010), and recent GRAIL results that clearly show spatial variations in crust density and porosity (Wieczorek et al., 2013). Thus, the broad range of acceptable mineralogical and thermal models may simply reflect 3D variations in the seismic data that have been mapped into 1D structure (necessarily, given the data set).

10.03.3 Seismic Activity of the Moon and Terrestrial Planets

10.03.3.1 Internal Seismic Activity

So far, no conclusive indication of present-day plate tectonic activity has been observed on a planet other than Earth. Moreover, only the Moon's seismic activity is constrained by seismic data, and the seismic activity of Mars and Venus can only be estimated from models based on faults density or theoretical thermoelastic cooling. During the Apollo seismic network's 7-year operating life, about 13 050 seismic signals were detected on the LP instruments and cataloged, and many more events recorded by the SP instruments remain uncataloged. **Figure 10** shows the annual detection statistics on the horizontal component of the Apollo 14 station, based on Nakamura's catalog. We focus first on the internal activity of the Moon, and then we address the internal activity of other planets, followed by a discussion of impact seismology.

Assuming that the largest deep moonquakes have a seismic moment of 5×10^{13} Nm and associated stress drops of about 10 kPa (Goins et al., 1981a), quakes with seismic moments 30 times smaller were detected. These smallest reported moonquakes correspond to terrestrial events with body-wave magnitudes as low as 1.6 and are detectable because of the low seismic noise level on the Moon (**Figure 1**). Note, however, that the definitions of the body- or surface-wave magnitudes are generally based on Earth conditions. Therefore, unless specified differently, we will use moment magnitudes directly related to the seismic moment by $M_w = \frac{2}{3}(\log_{10}(M_0) - 9.1)$, where M_w is the moment magnitude and M_0 the seismic moment in Nm (relation (4) of Hanks and Kanamori, 1979 after unit corrections).

Deep moonquakes originate from regions that appear to undergo repeated failure, giving rise to sets of moonquakes with similar waveforms and periodic occurrence times (Lammlein et al., 1974; Nakamura, 1978; Toksöz et al., 1977 and more recently, Frohlich and Nakamura, 2009; Weber et al., 2009). The number of known source regions for deep moonquakes is currently estimated at ~250 (Nakamura, 2003, 2005), and source depths range from 700 to 1200 km. **Figure 11(a)** shows the variation in the number of moonquakes recorded per week for the duration of the Apollo seismic experiment. The installation dates of the stations are provided in **Table 1**. The activity at all known moonquake nests (reported in Nakamura et al., 2008) is shown in red, and the activity recorded at nine clusters that dominate the catalog is shown in blue. **Figure 11(a)** illustrates that the activity at these nine well-studied clusters closely resembles the behavior of the larger deep-moonquake population. Individual peaks in the time series occur at approximately 2- and 4-week intervals. Also apparent is the modulation of moonquake activity during the 206-day period, and possibly during a period close to the duration of the experiment (6 years). **Figure 11(b)** shows the power spectrum of moonquake activity. The number of moonquakes per 24-h day was calculated, and the power spectrum was computed using the minimum-bias multitaper method of Riedel and Sidorenko (1995). A multitaper method was chosen because tidal effects with periods of 206 days and 6 years are suggested by the time series in **Figure 11(a)**. The 6-year period, in particular, requires the full length of the time series (8 years) to be analyzed. Various numbers of tapers were explored. **Figure 11(b)** shows the power spectrum computed using six tapers. This number allows frequency resolution at the expense of noisy spectral estimates, as is evident at high frequencies. Spectral peaks are seen at 13–14 and 27–28 days, with some structure seen in the monthly peak. A broad peak in the power spectrum is seen close to the previously noted 206-day period, and the increase

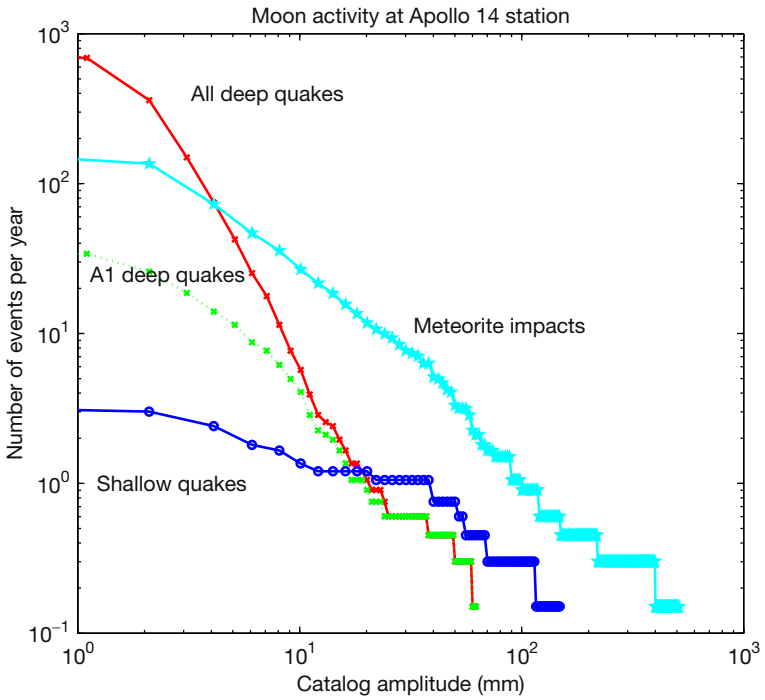

Figure 10 Number of events per year detected by the Apollo 14 station versus amplitude. The amplitudes are found in the Nakamura et al. (2008) catalog. The conversion of amplitudes in physical units depends on the instrument function response and on the dominant frequency. For a pure sinusoidal signal, the amplitude x (in mm) is about half of the amplitude of the time derivative of the signal y (in DU/s) (Nakamura, personal communication). At 1 Hz, which is the dominant frequency of the deep moonquakes recorded at Apollo 14, the resolution of the peaked mode is about 3.5×10^{-10} m, and a distance of 1 mm therefore corresponds to about 10^{-10} m in ground displacement. For high-frequency teleseismic and impacts, the scaling depends on the distance. Note the very high number of events detected per year in all cases, despite their very low amplitudes (see **Figure 1** for seismometer sensitivity).

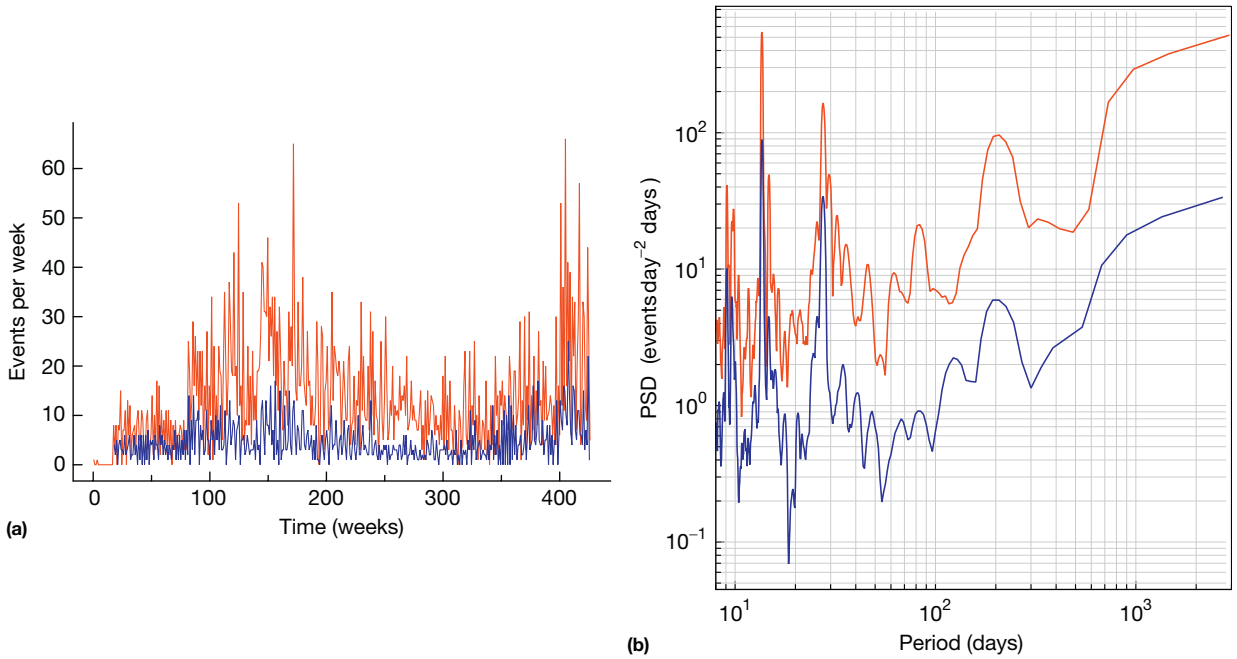

Figure 11 Deep-moonquake activity. (a) Number of moonquakes per week versus time in weeks, starting from the beginning of the seismic experiment. Moonquake activity, which is based on a recent update of the deep moonquake catalog (Nakamura et al., 2008), is shown in red. For comparison, the moonquake activity at nine of the most active deep clusters (A1, A6, A8, A9, A10, A14, A18, A20, and A33) is shown in blue. This moonquake activity includes new events recently found by Bulow et al. (2005, 2006) and not included in the lunar catalog (Nakamura et al., 2008). (b) Power spectral density (PSD) of the number of moonquakes per day versus period in days. Peaks at ~14, 28, and 206 days can be seen, and the power at the longest periods likely results from a 6-year modulation of moonquake occurrence times. Red and blue curves are as in (a).

in power at the longest periods likely reflects the 6-year modulation of moonquake occurrence times (Lammlein, 1977; Lammlein et al., 1974). Energy from this period is spread over the five lowest frequency spectral estimates, which occur at periods of 2916, 1458, 972, 729, and 583 days. Increased smoothing using more tapers or the fully adaptive multitaper approach results in spectra with broader peaks at the monthly and fortnightly periods and the loss of any resolution at around 200 days. Thus, this spectral approach, which is typically used in investigating tidal periodicities in terrestrial quakes (e.g., Tolstoy et al., 2002), provides only crude insight into the lunar data. In contrast, the spike train approach of Bulow et al. (2007) allows resolution of the distinct contributing monthly periods.

In addition to the deep quakes, 28 other events were detected at much shallower depths. These events may be analogous to terrestrial earthquakes. They show no obvious correlation with tidal activity or with surface features on the Moon, although no events in the southeast quadrant of the Moon's nearside were detected. (The latter observation is highly uncertain due to the paucity of observed shallow events.) All focal depths for the shallower events are <200 km. The largest shallow events have a seismic moment of about 3×10^{14} Nm for Goins et al. (1981a) or 1.6×10^{15} Nm for Oberst (1987), and the equivalent moment magnitudes range from 3.6 to 4.1. Their depths have been estimated to be <200 km, and they are interpreted as resulting from the release of tectonic stresses (Nakamura et al., 1982). Even the SP seismometers recorded flat displacement spectra, indicating a corner frequency higher than 10 Hz in most the cases (Goins et al., 1981a). This implies very high stress drops, ranging from less than 40 MPa for Goins et al. (1981a) to 210 MPa for Oberst (1987), perhaps due to the cold, volatile-poor (and hence rigid) lunar lithosphere. Interestingly, these events resemble Earth's intraplate earthquakes, which also exhibit stress drops (for a given seismic moment) much higher than the drops associated with plate boundary-related earthquakes (Scholz, 1990). (Intraplate earthquakes have been used as a reference for all estimates of seismic activity on the telluric planets).

We now examine how quakes can be released by the thermoelastic cooling of the lithosphere. We apply the theory to the Moon in order to possibly explain the shallow lunar events, and to Mars in order to predict possible background seismic activity. The cumulative seismic moment, over a time Δt, is given by

$$M_{\mathrm{cum}} = \eta \dot{\varepsilon} V \mu \Delta t \qquad [1]$$

where V is the seismogenic volume, η is the seismic efficiency, and μ is the mean shear modulus of the seismogenic layer (Bratt et al., 1985; Phillips, 1991). Following Phillips (1991), the strain rate $\dot{\varepsilon}$ is given as

$$\dot{\varepsilon} = \frac{1}{H\left(a-\frac{H}{2}\right)^2}\int_{a-H}^{a} \alpha \dot{T} r^2 \mathrm{d}r \qquad [2]$$

where H is the thickness of the seismogenic layer, α is the thermal expansion coefficient, $\dot{T}$ is the cooling rate, and a is the planetary radius. If we assume that the thermal gradient in the seismogenic layer is linear and given by $T=T_0+((a-r)/H)\Delta T$, and that H thickens with time at a rate, $\dot{H}$ (both $\dot{T}$ and $\dot{H}$ are counted positively), we then have

$$M_{\mathrm{cum}} = 2\pi\alpha\eta\mu a^2 H \Delta T\left(\frac{\Delta\dot{T}}{\Delta T}+\frac{\dot{H}}{H}\right)\beta\Delta t \qquad [3]$$

where ΔT is the contrast of temperature between the bottom of the seismogenic layer and the surface, and where

$$\beta = \left(1-\frac{H}{a}+\frac{1}{3}\frac{H^2}{a^2}\right)\frac{1-\frac{4}{3}\frac{H}{a}+\frac{1}{2}\frac{H^2}{a^2}}{1-\frac{H}{a}+\frac{1}{4}\frac{H^2}{a^2}} \qquad [4]$$

is a geometrical factor correcting the thin-shell approximation. This factor is greater than 0.95 for Mars, the Earth, and Venus, and it is 0.72 for the Moon.

For the Moon, we have assumed $H=400$ km, which is an estimate of the depth of the 1073 K isotherm (Spohn et al., 2001a). The isotherm corresponding to the base of the lunar seismogenic layer is unknown. Abercrombie and Ekström (2001) take 873 K as the limit of brittle failure in oceanic crust, and this temperature is reached at depths of about 250–300 km on the Moon, using the thermal models of Spohn et al. (2001a) and Gagnepain-Beyneix et al. (2006), respectively. None of the shallow moonquakes occurred at depths >200 km, however. On the other hand, the lunar crust might be rich in anorthite, and, in that case, the pressure and temperature at that depth might encourage the transition of feldspar from brittle to plastic, as happens at depths of 20–30 km in the Earth's continental crust (Scholz, 1990). Deep moonquakes occur at much greater depths, up to 1100–1200 km, where the temperature seems high (1600–1700 K) according to all published models. This relationship between deep-earthquake frequency and higher temperatures remains a paradox, either related to our models of the lunar interior, lunar mineralogy, or our current understanding of fault rupture under these conditions. Yet, as noted above, the energy released by deep moonquakes is limited compared to the energy released by shallow quakes.

For Mars, Phillips (1991) has assumed a constant cooling rate of $\dot{T}$ equal to 1.1×10^{-7} K year^{-1}, and using a thermal evolution model, Knapmeyer et al. (2006) have set the $\dot{T}$ value at 0.5×10^{-7} K year^{-1}. Taking the 873 K lower bound on the isotherm at the base of the seismogenic layer, and the thermal evolution models of Spohn et al. (2001b), we estimate $\dot{H}$ to be in the range 3.15×10^{-8} to 4×10^{-8} km year^{-1}. (For comparison, this is 10–20 times smaller than the rate of thickening of the 100 Ma oceanic lithosphere.) Using $\alpha=2\times10^{-5}$ K^{-1}, $\mu=66$ GPa (obtained for $v_s=4.5$ km s^{-1} and $\rho=3300$ kg m^{-3}) and 3.5×10^{-8} km year^{-1} for $\dot{H}$, $M_{\mathrm{cum/year}} = a\mu\Delta t 2\pi a^2 \dot{H}\Delta T \approx 5.5\times10^{17}$ Nm year^{-1}, a value to be compared with the annual release of the shallow quakes (7.3×10^{14} Nm year^{-1}). Such a rate is similar to the one obtained if constant $\dot{T}=0.5\times10^{-7}$ Kyear^{-1} is assumed for a 200-km seismogenic layer. The ratio between observations and the model is about 1.3×10^{-3}, 20 times smaller than the lowest seismic efficiency parameters η reported for Earth (e.g., Ward, 1998). Thus, the shallow seismic energy release of the Moon is an outstanding puzzle: calculations of the type above, modeled on the approach of Phillips (1991), are either inappropriate or require an extreme choice of parameters relative to our current understanding. Lunar seismic efficiency may be lower than on Earth, possibly due to a cold, volatile-free seismogenic layer

able to support large initial stress without rupture. On the other hand, if these calculations are correct, we cannot exclude shallow moonquakes of much greater magnitude, but with period of recurrence longer than the 7 years of operation of the Lunar Network.

The seismic activity of Mars is unknown and can be estimated only through a comparative approach involving the Moon, as shown in **Figure 12**. Researchers have proposed only one possible seismic event on Mars during the 19-month operation of the Viking Lander 2 seismometer (Anderson et al., 1977a,b). During most of the experiment, the seismometer signal was correlated with the wind-related vibrations and lift of the lander. (See Lognonné and Mosser (1993) for a detailed explanation, and Nakamura and Anderson (1979) for an application of the seismometer as a wind sensor.) As the proposed event was detected at a time when no meteorological wind data were recorded, this single detection is far from conclusive! Moreover, Goins and Lazarewicz (1979) have shown that, due to mantle attenuation on Mars, the 4-Hz frequency of the seismometer was not optimized for the detection of remote events, and martian seismic activity comparable to or lower than terrestrial intraplate activity was still compatible with this lack of detection.

Seismic activity lower than the Earth's intraplate activity is indicated by all available theoretical predictions. Golombek et al. (1992) use surface-fault observations, and Phillips (1991) uses a lithospheric thermoelastic cooling model to propose seismic activity on Mars 100 times greater than the shallow moonquake activity detected by the Apollo seismometers. The greater activity results from the effect of surface area (a factor of about 4), a seismogenic efficiency closer to Earth values (a factor of at least 20), and a possibly greater cooling rate (a factor of about 2). However, the amplitudes of the largest Mars seismic signals are still expected to be about four orders of magnitude lower than those of the largest earthquakes at LPs, that is, at frequencies below the source cutoff. **Figure 13** shows that martian seismicity might result in about 50 quakes with a seismic moment of 10^{15} Nm year^{-1}, with an increase–decrease of the quake frequency by a factor of 5 for a decrease–increase of the seismic moment by a factor of 10. This represents a cumulative seismic energy release of 10^{18}–10^{19} Nm year^{-1} (purple curve, **Figure 13**). These early estimates have been updated by Knapmeyer et al. (2006), with seismic activity ranging from a high seismic moment budget distributed over many events, to a low seismic moment budget distributed over a few events (**Figure 13**).

Although not modeled here, other sources of seismicity are possible. Volcanic activity, in the form of volcanic tremors or magma chamber retreat and associated faulting (e.g., as observed on Alba Patera by Cailleau et al., 2003), could lead to quakes, but although surface evidence for activity in the last 10 My has been proposed (Neukum et al., 2004), no evidence for present-day activity exists. The cooling of the most recently active volcanoes along with stresses associated with known gravity anomalies (e.g., at Argyre or Isidis (Zuber et al., 2000)) can supplement thermoelastic stresses. Landslides can also be associated with locally increased seismic activity. The distribution of potential tectonic quakes was studied by Knapmeyer et al. (2006) using the MOLA (Mars Orbiter Laser Altimeter) altimetry data. A total of about 7000 faults with a cumulative length of 600 000 km were found. Half of these faults appeared to be thrust faults, and the other half appeared to be normal, with no obvious correlation between fault density and ages. **Figure 14** shows the results of a Monte Carlo simulation of seismic activity on these faults, indicating

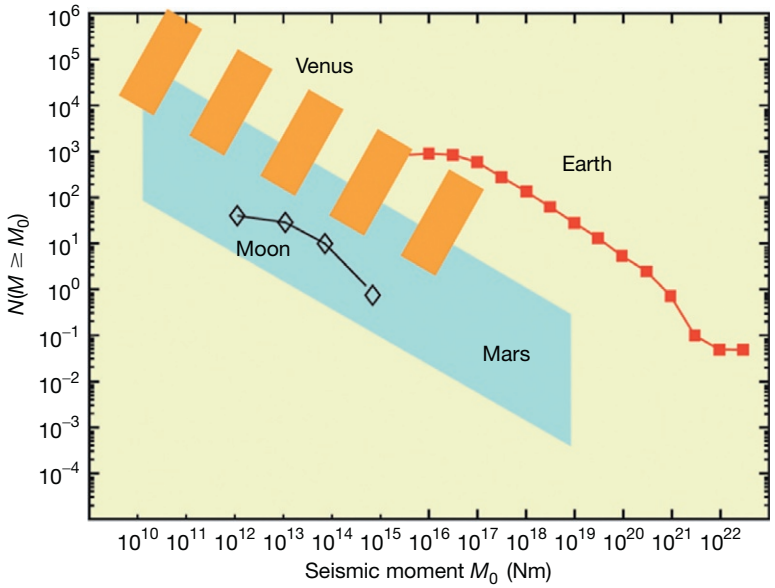

Figure 12 Seismic activity of the telluric bodies. The figure shows the annual number of events that are larger than a given seismic moment. For the Moon, the estimate is obtained from Oberst (1987) and only refers to shallow moonquakes. For Mars and Venus, the activity is estimated from various published models, based on the thermoelastic cooling of the lithosphere. The terrestrial activity is the mean activity for the period 1984–2004. The figure was adapted from results presented in Knapmeyer M, Oberts J, Hauber E, Wählisch M, Deuchler C, and Wagner R (2006) Working models for spatial distribution and level of Mars' seismicity. *Journal of Geophysical Research* 111: E11006.

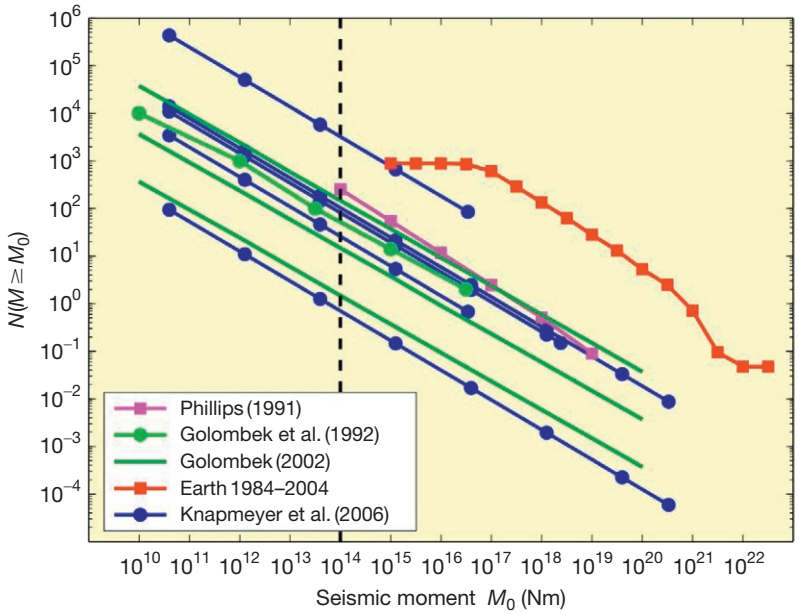

Figure 13 Comparison of models for annual martian seismic activity with the terrestrial mean annual activity (Knapmeyer, personal communication). Most models predict a total of 10–100 quakes per year with moments larger than 10^{15} Nm. The dashed line represents quakes of moment 10^{14}, for which S and P body waves have typical amplitudes of about 10^{-9} ms^{-2} in the 0.1–1 Hz bandwidth, with peak-to-peak distances of 50° and 70°, respectively (see **Figure 33(b)**). These waves may therefore be at the limit of detection for estimated martian noise levels (Lognonné et al., 2000). The two green lines shown for Golombek et al. (1992) and the blue line for Knapmeyer et al. (2006) refer to different hypotheses regarding the seismicity.

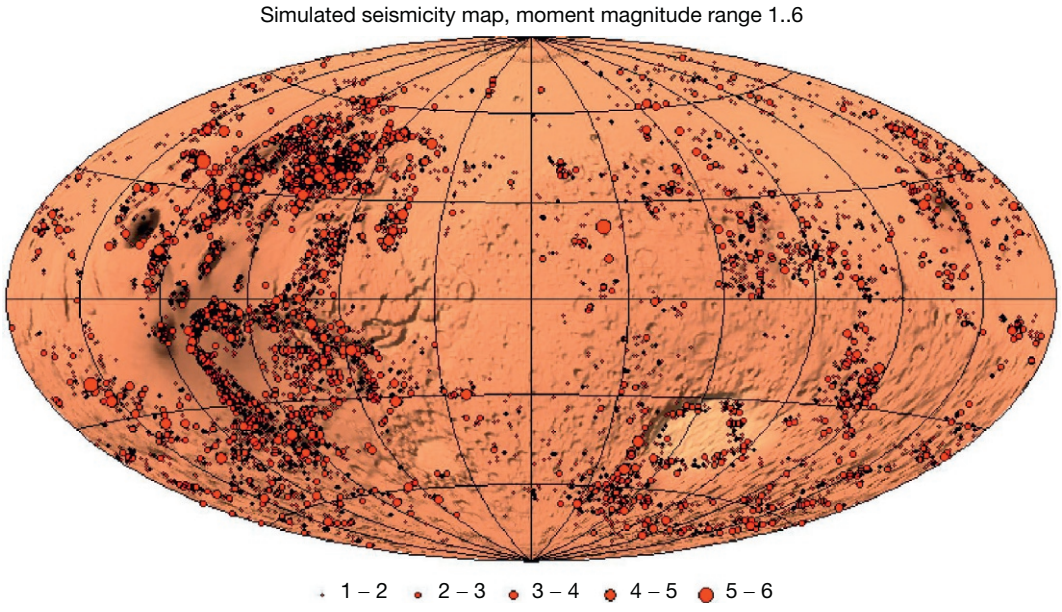

Figure 14 Seismicity map of Mars from Knapmeyer et al. (2006), determined using a Monte Carlo simulation of seismic activity releasing a cumulative moment of 10^{18}–10^{19} Nm per year (from Golombek et al., 1992), and with a probability distribution of epicenter locations determined by the density of surface faulting. The map shows the distribution of marsquakes that might be expected during one Earth year, with an annual seismic budget between the upper and lower bounds (Knapmeyer, personal communication).

that activity in the Tharsis region is very likely (Knapmeyer et al., 2006).

We briefly mention seismicity estimates for two other planets that might be targeted for seismic missions in the coming decades: Venus and the Jovian satellite Europa. Estimation of the seismic potential activity of Venus, performed as part of the NASA Venus Internal Structure Mission study (Stofan et al., 1993), suggested a seismically active planet. Assuming a seismogenic layer of 30 km, more than 100 quakes of $M_w > 5$ could be released by intraplate activity with a strain rate of 10^{-19} s^{-1} (Grimm and Hess, 1997). Quakes with $M_w > 6$ might be five times less frequent. A suggested rise in surface

temperature on Venus, over the period for which we have a geological record, generates compressive thermoelastic stresses in the crust (Dragoni and Piombo, 2003; Solomon et al., 1999). Such stresses might either generate reverse faults or act on preexisting reverse faults, and, by analogy with Earth, these stress might lead to quakes of maximum moment magnitude 6.5. A complicating issue on Venus is that of rheology; the absence of volatiles means that crustal rocks are much stronger than their terrestrial counterparts (Mackwell et al., 1998). Finally, as we note in our concluding remarks, there are severe technical challenges facing surface-based seismological experiments on Venus.

The seismic activity of the Jovian satellites is also unknown, although Io could be the most active of all known satellites in the Solar System (Kuskov and Kronrod, 2000) and a perfect target for a seismological mission. The possible activity of seismic activity on Europa has been reviewed by Panning et al. (2006), following studies of Kovach and Chyba (2001) and Lee et al. (2003) on the possibility of seismic experiments on this satellite of Jupiter. Possible seismic sources on Europa include the opening of tensile cracks due to the Jovian tides, as tide-induced cracks might lead to quakes ranging from 2 to 4 in moment magnitude. Nimmo and Schenk (2006) have also identified regions of normal faults on Europa by analyzing Galileo data, indicating potential quakes up to $M_w = 5.3$ magnitude. The frequency of such proposed events remains unknown.

10.03.3.2 External Seismic activity: Artificial and Natural Impacts

Impacts constitute about one-fifth of the seismic events detected by the Apollo network (1742 of the 9315 identified and classified events), and the strongest impact events have amplitudes comparable to the largest moonquakes. As discussed in **Section 10.03.2**, these surface seismic sources permit more detailed studies of crustal seismic structure, including lateral variations in thickness (Chenet et al., 2006).

The ability of meteorite impacts to generate seismic waves has been widely discussed regarding impacts on the Moon (Laster and Press, 1968; Latham et al., 1970b; Lognonné et al., 2009; McGarr et al., 1969), on Mars (Davis, 1993; Teenby and Wookey, 2011), and on asteroids (Ball et al., 2004; Richardson et al., 2004; Walker and Huebner, 2004). Large uncertainties remain when estimating the best value for seismic efficiency, which is the ratio between impact kinetic energy and radiated seismic energy, and values range from 10^{-6} to 10^{-4}, leading to an order-of-magnitude uncertainty in the amplitude of impact-generated seismic waves.

In practice, at teleseismic distances, only LP waves are detected, and the equivalent source of a meteorite impact is a point-force seismic source (Lognonné et al., 2009; McGarr et al., 1969). For low-velocity impacts, the amplitude below the impact cutoff frequency is proportional to the linear momentum of the impactor, while, for larger velocities, the amplitude is increased by up to a factor of 2 due to impact-generated ejecta (Lognonné et al., 2009). These LP source models have been tested successfully with the Apollo seismic data recorded during the controlled impacts of the Saturn V upper stages and the Lunar Modules (see, e.g., the seismic records of the Apollo 17 upper stage, shown in **Figure 15**, with a momentum of about 37 000 kg km s^{-1} (14 487 kg at 2.55 km s^{-1})), and the LP models have been used to estimate the momentum of natural impacts on the Moon (Gagnepain-Beyneix et al., 2006; Gudkova et al., 2011). The amplitude of the largest impacts was estimated by Gagnepain-Beyneix et al. (2006), and models indicate that thes impacts typically release a seismic impulse up to almost 10^9 Ns. This impulse is a factor of 25 larger than the Apollo Saturn V upper-stage impact. Relatively low cut-off frequencies (e.g., up to 1 s) have been found, likely related to the radiation time of the impact-generated shock wave (Gudkova et al., 2011).

The advantage of studying impact-related seismic activity is the reduced number of focal parameters, which are limited to geographical location and time. Moreover, for artificial impacts, these quantities are determined with high precision because the impacts can be radio-tracked. This level of accuracy was achieved for most of the lunar impacts (with the exception of the SIV-B 16 impact, which suffered from a radio-tracking failure), and the precise locations of the artificial impacts have also been confirmed by LRO imaging (e.g., Wolf et al., 2012). As an alternative to artificial impacts, Lognonné et al. (2009) and Yamada et al. (2011) recently proposed monitoring the flashes generated by impacts (e.g., Bouley et al., 2012; Ortiz et al., 2006; Suggs et al., 2008) on the near side and even the far side of the Moon (Mimoun et al., 2012) in order to obtain impact data for future lunar seismic experiments.

Even if the locations of natural impacts are not known, these events are still very useful seismic sources. In the case of the Moon and Earth, and more generally for the terrestrial planets (Le Feuvre and Wieczorek, 2008), the frequency and size of impactors can be obtained using the statistical properties of the Earth-crossing asteroids (e.g., Poveda et al., 1999) and collision rates (e.g., Brown et al., 2002; Shoemaker et al., 1990). Such an approach allows for the modeling of impact frequencies on terrestrial planets that can then be calibrated to the lunar impact-generated seismic noise, using the ALSEP seismic data (Lognonné et al., 2009).

The Moon enables the calibration of impact amplitude and frequency. Typically, impacts have been detected at a rate of about 150 per year, with different detection rates among different Apollo stations resulting from differences in local (site) amplification (Lognonné et al., 2009). The spectrum varies as $A_0 I f^3 / D$, where I is the impulse, f the frequency, D is the epicentral distance, and A_0 depends on the temporal length of the window used for the spectrum computation (Gudkova et al., 2011). For the lunar diffusive case and a window of 5000 s, A_0 is typically found to be 1.1×10^{-12} ms^{-2} Hz$^{-1/2}$, but A_0 can have larger values for shorter windows that are comparable to the rise time of the seismic coda.

As shown by Lognonné et al. (2009), the seismically observed impact rates are well retrieved by a Monte Carlo simulation of impacts constrained by the impact flux rate. **Figure 16(a)** shows the result of such a simulation for different bandwidths, when the spectrum of the signal is as described above and the detection rate is 50 events per year. Over the 7 years of operation, the largest impacts estimated by Gagnepain-Beyneix et al. (2006) and Gudkova et al. (2011) typically released a seismic impulse in the range 10^8–10^9 Ns. This is a factor 10–100 times larger than the Apollo Saturn V upper-stage

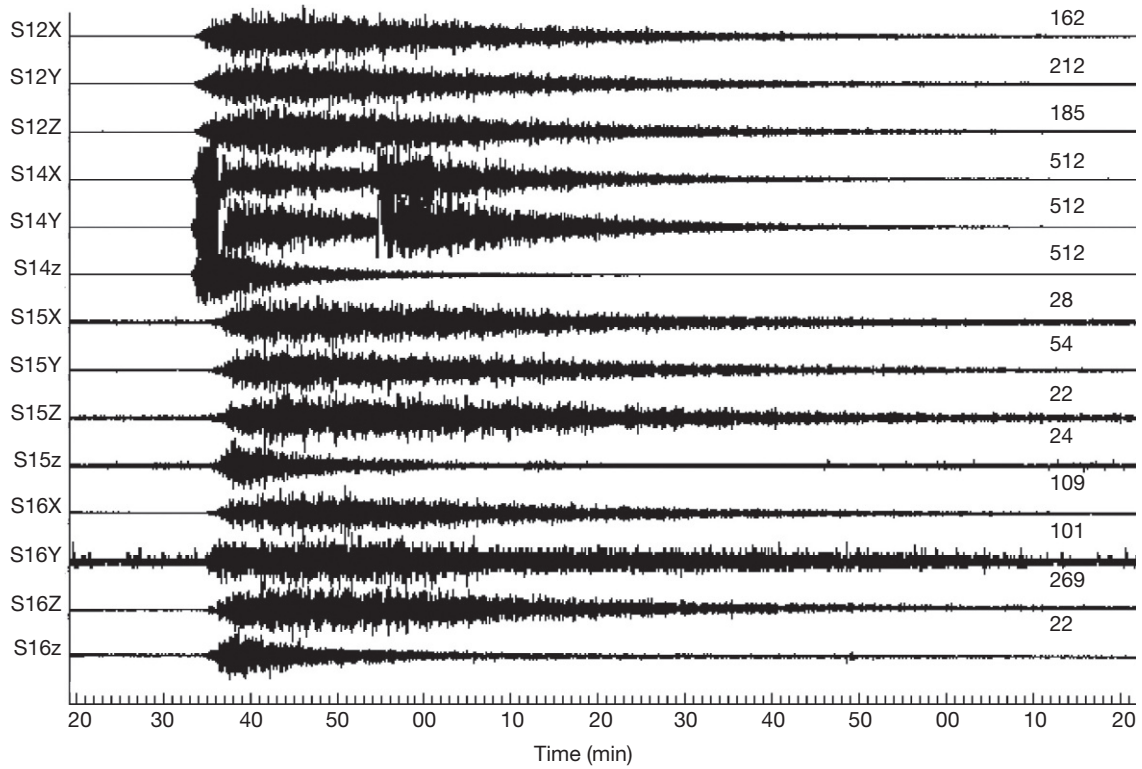

Figure 15 Apollo seismic network records, in digital units, for the impact of the Apollo 17 Saturn V upper stage (Saturn IVB) on the Moon on 10 December 1972 at 4.21° S, 12.31° W (at distances of 338 km from the Apollo 12 station (S12), 157 km from the Apollo 14 station (S14), 1032 km from the Apollo 15 station (S15), and 850 km from the Apollo 16 station (S16)). For each station label, X, Y, and Z represent the LP seismometers, z is for the SP seismometer, and transfer functions are given in **Figure 1**. Amplitudes at the Apollo 14 station, 157 km from impact, are saturated largely due to S waves trapped in the regolith. The first P arrival is typically ten times smaller. Note the 10-db gain change at the middle of the fourth and fifth traces. Reprinted from Lognonné P (2005) Planetary seismology. *Annual Review of Earth and Planetary Sciences* 33: 19.1–19.34. doi:10.1146/annurev.earth.33.092203.122605, with permission of Annual Review of Earth and Planetary Sciences.

impact, and a few hundred times larger than the Lunar Module impact. On the other hand, assuming impacts at 20 km s^{-1}, **Figure 17** shows a typical detection mass threshold of about 100 kg. The detection of smaller impacts requires SP seismometers with sensitivity significantly better than Apollo (e.g., Yamada et al., 2011, 2013).

On planets with an atmosphere, the velocity and the mass of the impactors are reduced during atmospheric entry. This effect can be assessed by integrating the impactor equation in the atmosphere (Chyba et al., 1993; Poveda et al., 1999):

$$m\frac{dv}{dt}=\frac{1}{2}C_D\rho v^2A-mg$$
$$\frac{dm}{dt}=\frac{1}{2}\frac{C_H}{Q}\rho v^3A \qquad [5]$$

where m is the mass of the meteoroid, v is its velocity, ρ is its density, g is the gravitational acceleration, C_D is the drag coefficient (here taken as 1.7, the cylinder value), C_H is the heat transfer coefficient (taken as 0.1), Q is the heat of ablation of the meteoroid (taken as 10^7 J kg^{-1}), A is its cross section, and t is time. **Figure 16(b)** shows the effect of the Mars atmosphere on Mars-impacting meteoroids, with an asteroid density of 2400 kg m^{-3}. The atmospheric shielding effect on Mars is small for the largest events, as it is on the Earth at altitudes of 30 km or higher (ReVelle, 1976) where the pressure is comparable that measured on the martian surface. The model of Le Feuvre and Wieczorek (2008) is used. The entry flux of meteorites is 2.6 times larger than the flux on Earth due to the proximity of the asteroid belt (e.g., Davis, 1993), but the increased flux on Mars is balanced by the impact velocity, which is about half the impact velocity on Earth. The upper number of impacts per year detected by a seismic station on Mars might therefore be comparable to that on the Moon (Davis, 1993), and Martian impacts have been estimated to generate about ten seismic events per year with an amplitude larger than 3×10^{-9} m s^{-2} (**Figure 17**). These seismic events would be associated with impacts of objects having masses of several hundred kilograms, at impact velocities about twice the velocities of lunar impacts.

Most of the differences between impact-related seismic activity on Mars and the Moon are expected to be associated with contrasting crustal seismic attenuation. The attenuation for Mars remains unknown, but it is likely less than the attenuation on Earth. In addition to seismic waves generated by an impact, the interaction of a meteor blast with the martian surface might be a significant source of additional seismic signals through air-coupled Rayleigh waves and direct airwave coupling (Edwards, 2008). Such surface vibrations have been proposed as a preferred source for dust avalanches (Burleigh et al., 2012), rather than pure seismic shaking (Chuang et al., 2007).

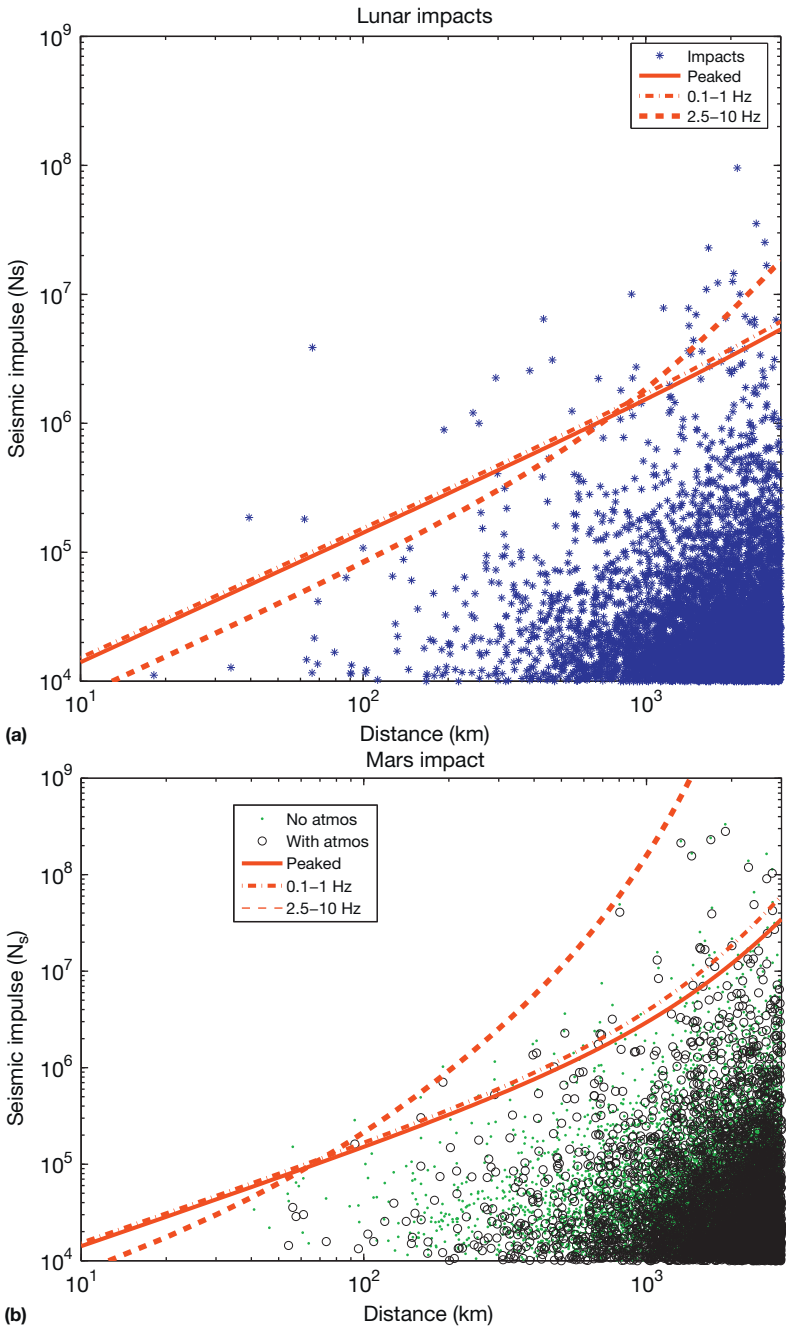

Figure 16 Impact simulation for asteroid impacts on the Moon (a) and Mars (b). The rate of impacts is from Ortiz et al. (2006) and follows the statistical approach of Le Feuvre and Wieczorek (2008), with seismic amplitudes estimated using the approach described by Lognonné et al. (2009). The detection thresholds are based on a signal-to-noise ratio of 3 and flat noise levels of 3×10^{-10} ms^{-2} Hz$^{-1/2}$ in the 0.33–0.75 Hz bandwidth, 5×10^{-10} ms^{-2} Hz$^{-1/2}$ in the 0.1–1 Hz bandwidth, and 10^{-8} ms^{-2} Hz$^{-1/2}$ in the 2.5–10 Hz bandwidth. The first and the last frequency bands are comparable, but not identical, to the Apollo peaked LP and SP detection threshold. For the LP peaked case, this translates into peak-to-zero signal amplitudes of approximately 1.5 DU or 2 mm, where DU $= 0.5 \times 10^{-10}$ m, or ground displacement. The mm value is the amplitude from the Namamura catalog. For the Moon (a), amplitudes have been calibrated with Apollo data and assume a low attenuation ($Q = 5000$) and $v_s = 4.5$ km s^{-1}. For Mars (b), small green dots are impact impulses without atmospheric ablation, while circles represent impulses with atmospheric ablation. Attenuation is corrected by assuming a $Q = 600$ and a shear velocity of $v_s = 4.5$ km s^{-1}, which leads to a corrective factor of $\exp(-\omega t/2Q)$, where $t = D/v_s$. Given a smaller diffusion–scattering than is present on the Moon, larger amplitudes are very likely but not accounted for in these amplitude estimates.

Lastly, we consider small bodies. Currently, the experiment SESAME/CASSE is onboard the Rosetta mission to comet 67P/Churyumov–Gerasimenko (Seidensticker et al., 2007), with a landing expected in 2014. This experiment aims to investigate the outermost surface of the comet by means of active and passive acoustic-wave monitoring in a frequency range from a few hundred hertz to several kilohertz, and the mission may reopen the study of small-body seismology after

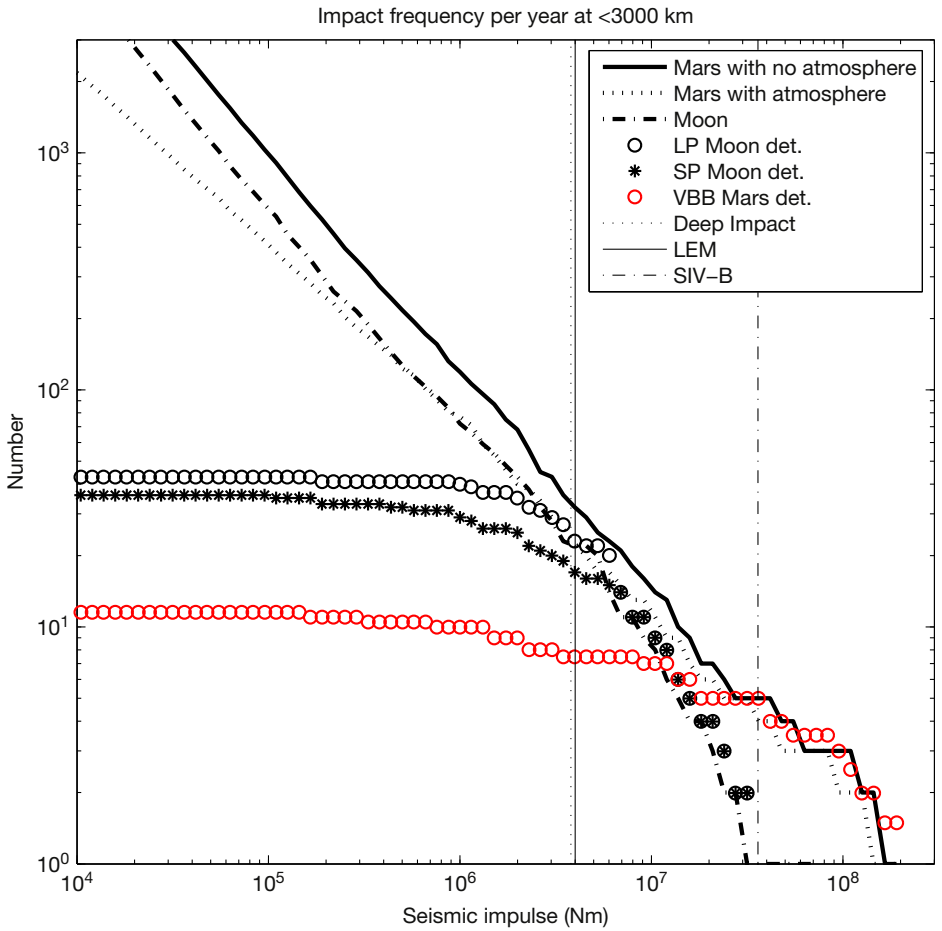

Figure 17 Simulation presented in **Figure 16**. For the Moon and Mars, the detection statistics are the cumulative number of events detected over a distance of 3000 km. The example shown corresponds to a cumulative rate of about 40 detections on the Moon with peak-to-peak amplitudes of 3 DU on the peaked LPZ. This corresponds to the minimum detection rate observed at the Apollo stations, while the maximum rate is about two times larger (see Figure 2 of Lognonné et al., 2009 or **Figure 10** for Apollo 14). Vertical lines provide the impulse values for the Apollo artificial impacts (see Gudkova et al., 2011) and the deep impact performed by the Stardust-NExT (A'Hearn et al., 2005; Schultz et al., 2013). Large uncertainties for Mars remain.

the failure of acoustic sensors onboard the Phobos 1 and 2 landers (Surkov, 1990). Both internal (related to degassing events) and external sources might generate seismic signals on comets, in contrast to asteroids for which only impacts are expected to cause seismicity. Future missions may be targeted toward asteroids, either to study the interior or as a deflection strategy in asteroid mitigation (Ball et al., 2004). Both active seismology (using explosives or impactors) or passive seismology (with natural impacts) have already been proposed (e.g., Walker and Huebner, 2004). Due to their limited size, these bodies have low gravity. As a consequence, minor impacts on asteroids produce ground accelerations higher than the local gravity, and seismic reverberation may have a major effect on the morphology of the asteroid regolith, including the shape and density of small craters (Richardson et al., 2004). The amplitudes of the body's impact-generated P and S seismic waves can be estimated with simple models. Scattering processes will affect body-wave amplitudes, and the irregular asteroid surface will strongly affect the amplitudes of surface waves.

For large impacts, such as the artificial impacts made in the Deep Impact mission (3.8×10^6 Ns by the impact of 370 kg at 10.2 km s^{-1}) (A'Hearn et al., 2005) or those expected in the Don Quijotte mission (4×10^6 Ns by 400 kg at 10 km s^{-1}) (e.g., Ball et al., 2004), the displacement amplitude of body waves can be roughly expressed by:

$$a_p = \frac{F\left(t - \frac{r}{c_p}\right)}{4\pi\rho c_p^2 r} \quad \text{and} \quad a_s = \frac{F\left(t - \frac{r}{c_s}\right)}{4\pi\rho c_s^2 r} \qquad [6]$$

where c_p and c_s are P and S velocities, ρ is bulk density, r is radial distance (Aki and Richards, 2002), and F refers to the point-force source functions (in N). By scaling the impact probability of **Figure 16** by the ratio of the the bodies' surface areas, we see that these impacts, on a 5-km-radius asteroid (i.e., with about 8×10^{-6} less surface area than the moon), will occur naturally at a rate of about one event every 4000–5000 years for an Earth-crossing asteroid flux, and the impacts will generate accelerations in the range of 0.01–1 ms^{-2}, depending on frequency. These accelerations are greater than the local gravity, and seismic reverberations will therefore affect the morphology of the asteroid regolith, including in the shape

and density of small craters (Richardson et al., 2004). As the frequency of impacts is typically a power law function of diameter, with a power law exponent of −5/2 (e.g., Poveda et al., 1999) (and hence a power-law function of mass, with exponent −5/6), accelerations 10^6 times smaller (in the range of 1–100 ng) will occur at a rate 10^5 times higher at 1 AU, and possibly even higher rates will occur at longer distances from the Sun. This translates into rates of hundreds of events per year, which could possibly be recorded by space-qualified SP seismometers. Such natural impacts might provide excellent seismic sources for tomography studies of asteroids (Roark et al., 2010).

10.03.4 Atmospheric Seismology

10.03.4.1 Theoretical Background

Over the last decade, many observations in terrestrial seismology have shown that the coupling between the atmosphere and the solid part of the Earth leads to an exchange of seismic energy between the two subsystems. For example, atmospheric-solid body coupling has been detected in the form of seismic signlas in the ionosphere. As shown by Lognonné et al. (1998b), a small fraction of the seismic energy in the lithosphere escapes into the atmosphere at frequencies higher than 3.7–4.4 mHz. Near the seismic source, the generated acoustic waves propagate as a plume that can reach the high atmosphere after being amplified by the exponential decay of the atmospheric density (Kelley et al., 1985). At greater distances, acoustic waves are primarily generated by Rayleigh surface waves and lead to ionospheric oscillations. These oscillations were first detected in the 1960s, following very large quakes (e.g., Davis and Baker, 1965; Leonard and Barnes, 1965; Weaver et al., 1970; Yuen et al., 1969), and they are now more commonly observed for quakes with magnitudes >7–7.5, using global positioning system (GPS) (Calais and Minster, 1995; Ducic et al., 2003; Garcia et al., 2005a) or Doppler sounders (Artru et al., 2001, 2004).

The excitation of seismic waves by volcanic eruptions (e.g., Kanamori et al., 1994; Lognonné, 2009; Zürn and Widmer, 1996) and the continuous excitation of normal modes (Kobayashi and Nishida, 1998; Suda et al., 1998; Tanimoto et al., 1998), called Earth's hum, have been proposed as other examples of such atmospheric coupling, that time with transfer from atmospheric sources to observation at the surface of the solid Earth.

In the case of Earth's hum, the amplitudes of the seismic signals are small, ranging from 0.3 to 0.5 ng (10^{-11} m s^{-2}) between 2 and 7 mHz, but, nonetheless, the signals are strong enough to allow for the identification of the resonance peaks of the fundamental normal modes. Early studies proposed that turbulences in atmospheric boundary layers (Nishida et al., 2000; Tanimoto, 1999) were strong enough to generate the observed signal. Recent studies show, however, that the source is located over the oceans (Rhie and Romanowicz, 2004, 2006; Tanimoto, 2005) and that infragravity waves over the continental shelves are much more likely seismic sources (Webbs, 2007). In summary, the Earth's hum seems to result from several coupling effects through which energy from the atmosphere is first transferred into oceanic infragravity waves and finally to the Earth's interior. If such a transfer is more efficient than the direct excitation of the normal modes by the atmosphere, what will be the case for a planet without ocean?

This question is addressed regarding Earth's two nearest neighbors, for which comparable energy is transferred into the atmosphere by the Sun. The solar flux driving atmospheric fluid layer circulations is proportional to $(1-A)/D^2$, where D is the distance to the Sun and A is the bond albedo (de Pater and Lissauer, 2001). The relative ratios of the Venus and Mars fluxes to the Earth flux are 0.67 and 0.51, respectively, and these flux ratios demonstrate the need to quantify the seismic energy-conversion efficiency for planets without oceans.

As we will see, the previously discussed topics might offer tremendous opportunities for new seismological discoveries. For Mars, continuous excitation of free oscillations, if strong enough, could enable the determination of fundamental mode frequencies, even if no large quake is directly detected. For Venus, remote detection in the atmosphere might provide the opportunity to perform seismic measurements, avoiding the major challenges associated with a long-lived lander able to withstand the planet's 500 °C surface temperature. More generally, any planetary body with an atmosphere will exhibit acoustic–seismic coupling between the atmospheric and interior parts of the planet. Other bodies of particular interest in this regard include Titan and the giant planets, for which no discontinuity exists between the interior and the atmosphere. Therefore, in this section we explore atmospheric coupling on Mars and Venus, focusing on the expected amplitude of signals. We then provide a short review of the status of giant planet seismology, for which the first seismic observations are yet to be performed.

We start by reviewing the main properties related to surface-atmosphere seismic coupling. The density and sonic speed for the lowest 150 km of the Earth, Venus, and Mars atmospheres are given in **Table 2** and **Figure 18**. The theory of interior-atmospheric coupling must first take into account the fact that a fraction of the seismic-wave energy is transmitted into the atmosphere when the seismic wave reaches the surface of the solid (or for the Earth, liquid) planet. For a vertically incident

Table 2 Atmospheric coupling parameters for Venus, Earth, and Mars

	Crust	*Earth*	*Mars*	*Venus*
Surface sound speed (m s^{-1})	5800	340	214	426
Surface density (kg m^{-3})	2600	1.225	0.0175	65
Acoustic impedance ratio/crust	1	2.76e−5	2.48e−7	1.83e−3
Energy transfer $\left(E=\frac{Q}{\pi}\frac{\rho_{air}c_{air}}{\rho_{int}c_{int}}\right)$ $(Q=100)$		8.8e−4	7.9e−7	5.8e−2
High-Q atmospheric resonances (mHz)		3.7	2.05	3.10; 4.15

The atmospheric model used for Earth is the US Reference Atmospheric model. For Mars, the atmospheric model is the mean model from a GCM run of Forget et al. (1999).

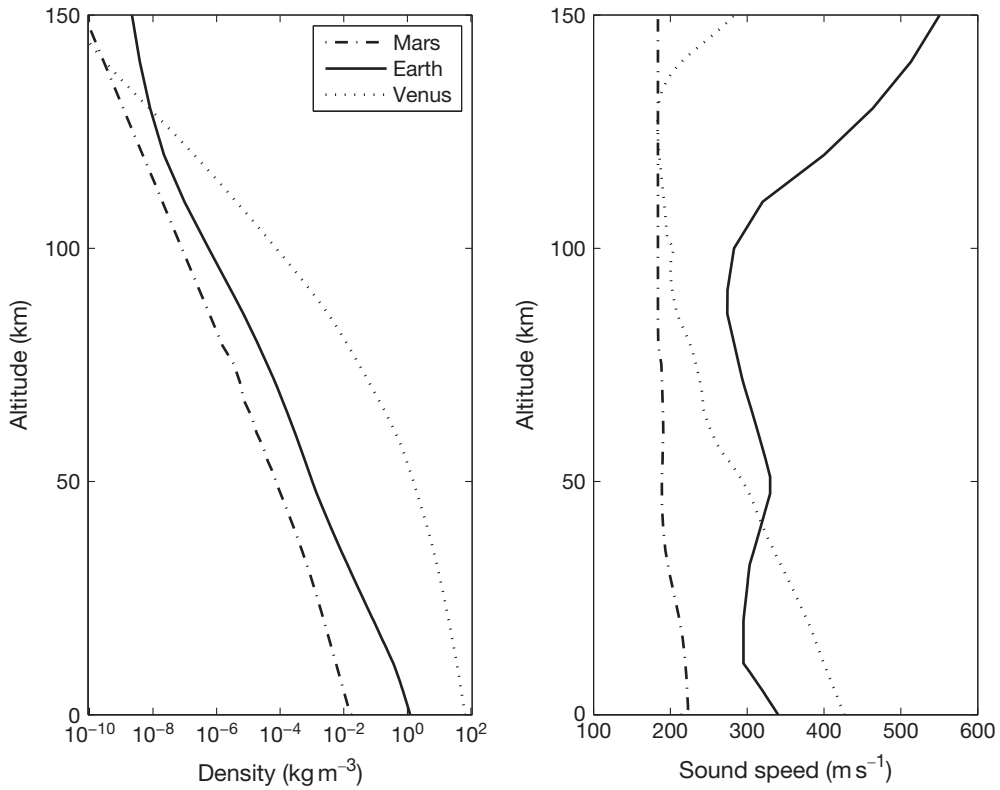

Figure 18 Atmospheric models of the Earth, Mars, and Venus used for the computation of atmospheric coupling. Note that these models are sensitive to the local time and latitude, as well as to the solar environment. The US standard atmospheric model (1976) is used for the Earth, whereas the models of Forget et al. (1999) and Hunten et al. (1983) are used for Mars and Venus, respectively.

acoustic wave, the amplitudes of transmission (t) and reflection (r) coefficients from the interior to the atmosphere are given by:

$$t = \frac{2\rho_{\text{int}}c_{\text{int}}}{\rho_{\text{air}}c_{\text{air}} + \rho_{\text{int}}c_{\text{int}}} \approx 2$$
$$r = \frac{\rho_{\text{int}}c_{\text{int}} - \rho_{\text{air}}c_{\text{air}}}{\rho_{\text{int}}c_{\text{int}} + \rho_{\text{air}}c_{\text{air}}} \approx 1 \qquad [7]$$

while the energy transmission (T) and reflection (R) coefficients are

$$T = \frac{\rho_{\text{air}}c_{\text{air}}}{\rho_{\text{int}}c_{\text{int}}}t^2$$
$$R = r^2 \qquad [8]$$

and $R+T=1$. The initial amplitude of the waves in the atmosphere is therefore twice the vertical amplitude of the waves (or the amplitude of the ground, due to continuity), while the relative transmitted energy is four times the acoustic impedance ratio. Surface waves of angular order ℓ have a horizontal wavelength of $\lambda = 2\pi a/(\ell+1/2)$ and will bounce on the surface once per cycle, with amplitude decreasing each time by $e^{-\pi/Q}$ due to attenuation in the solid part, where Q is the quality coefficient of the mode. Thus, during these successive bounces, the portion of the energy transmitted into the atmosphere will be $E = e(2Q/\pi)(\rho_{\text{air}}c_{\text{air}}/\rho_{\text{int}}c_{\text{int}})$, where e is the partition ratio between the energy in vertical displacement and the total energy, the latter being typically around 0.5. Such energy transmission, given in **Table 2**, is approximately found in the high ℓ limit of **Figure 19**.

In the atmosphere, in the non-viscous case, the seismic wave equation is given by:

$$\rho_0 \frac{\partial \vec{v}}{\partial t} = -\vec{\nabla} p + \rho_1 \vec{g}_0 + \rho_0 \vec{g}_1$$
$$\frac{\partial \rho_1}{\partial t} + \text{div}\left(\rho_0 \vec{v}\right) = 0$$
$$\text{div}\left(\vec{g}_1\right) = -4\pi G\rho_1$$
$$\frac{\partial p}{\partial t} = -\gamma p_0 \text{div}\left(\vec{v}\right) - \rho_0 \vec{g}_0 \cdot \vec{v} \qquad [9]$$

where ρ_0, ρ_1, and p are the equilibrium density, perturbation in density, and pressure, respectively, and where $\vec{v}$, $\vec{g}_0$, and $\vec{g}_1$ are the velocity, equilibrium gravity, and perturbation in gravity associated with the mass redistribution. p_0, γ, and G are the equilibrium pressure, the adiabatic index, and the gravity constant. The upward propagation of the waves is modeled by renormalizing the amplitudes in order to account for the exponential decay of the density. Quasianalytical expressions can be obtained when the atmospheric structure has a vertical scale much larger than the wavelength of the wave and when pure upward propagation is assumed. Gough (1986) shows that under these conditions eqn [9] leads to

$$\left(\frac{\partial^2}{\partial t^2} + \omega_c^2\right)\frac{\partial^2 \psi}{\partial t^2} - c^2 \frac{\partial^2}{\partial t^2}\nabla^2 \psi = 0 \qquad [10]$$

where the cutoff frequency is given in first approximation by $\omega_c = c/2H_\rho$ and where $\psi = c^2\sqrt{\rho_0}\text{div}\left(\vec{v}\right)$ is related to the

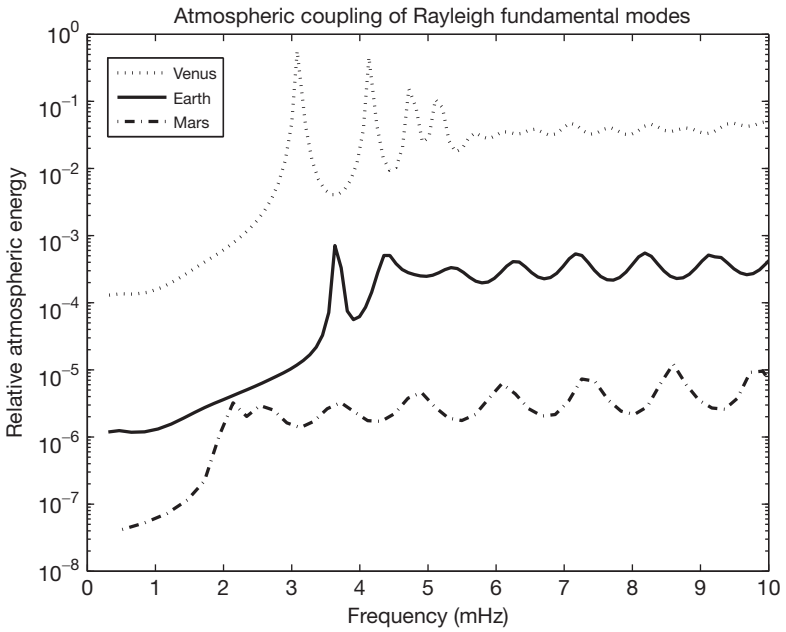

Figure 19 Fraction of the surface-wave energy in the Venus, Earth, and Mars atmospheres for Rayleigh surface waves. Only the first peaks are due to atmospheric resonances. Note that the amplitudes on Mars and Earth are comparable at low frequency (2–3 mHz) due to differences in the atmospheric resonance frequency.

square root of the acoustic energy $c\gamma_0 p_0 \mathrm{div}^2\left(\vec{v}\right)$, with $c^2 = \gamma_0 p_0/\rho_0$ being the squared speed of sound. Here, H_ρ is the density height scale given by $H_\rho = -(\mathrm{d}\,\mathrm{Ln}\,\rho/\mathrm{d}r)^{-1}$. The plane wave solution to eqn [10] obeys the dispersion equation:

$$\omega^2 = \omega_c^2 + k^2 c^2 \qquad [11]$$

Waves with frequencies lower than the cutoff frequency have negative k^2 and exponentially decaying energy in the atmosphere. Waves with frequencies higher than the cutoff frequency can propagate upward. This energy is not trapped, and the waves progressively lose energy during their upward propagation through viscous and nonlinear processes. Note that other parameterizations are possible, leading to slightly different expressions for the dispersion equation and cutoff frequencies (Beer, 1974; Mosser, 1995). The trapping of free oscillations, which can be used to model the waves with summation techniques, can be modeled when the full system (i.e., the solid and atmospheric parts of a planet) is considered, and when a radiating boundary condition (Lognonné et al., 1998b) is assumed at the top of the atmosphere. We provide the results of forward modeling based on this theory for Earth, Mars, Venus, and Jupiter.

For planets with solid parts, the normal modes of the system can be computed for spheroidal solid modes, atmospheric acoustic modes, and atmospheric gravity modes. The summation of these normal modes then allows the computation of either seismograms for the solid surface and for the atmospheric perturbations or barograms for the atmosphere as a function of altitude. More details and the theoretical background can be found in Lognonné et al. (1998b) and Lognonné and Clévédé (2002). An extension of these coupling models to the viscous case is given by Artru et al. (2001). Figure 19 illustrates the efficiency of coupling for Venus, Mars, and Earth, and it shows the fraction of energy of the fundamental Rayleigh modes in the atmosphere when the latter are computed with consideration given to atmospheric coupling. Resonance effects appear with a peak in the atmospheric energy; they are observed at frequencies associated with the fundamental and overtones of the atmospheric waves guide and are dependent upon the atmospheric model used.

At these frequencies, a much larger fraction of the seismic waves is transferred into the atmosphere. On Earth such resonance frequencies between the atmosphere and interior exist near 3.7 and 4.44 mHz and are preferential windows for studying atmospheric-interior coupling. Large atmospheric eruptions, such as those of El Chichon in 1982 and Pinatubo in 1991, led to selective excitation of Rayleigh surface waves at these frequencies (Kanamori and Mori, 1992; Widmer and Zürn, 1992; Zürn and Widmer, 1996). The fundamental resonance frequency on Mars is found at about 2.05 mHz, while the fundamental frequency and the three next overtones on Venus are found at 3.10, 4.15, 4.75, and 5.15 mHz. On Venus the two first overtones are strongly trapped while only the fundamental branch is trapped on the Earth and Mars.

Figure 20 shows the Rayleigh normal modes for angular orders smaller than 50. Below the atmospheric fundamental frequency, amplitudes decay with altitude, and full trapping of the modes is observed. At higher frequencies, oscillations appear as a consequence of the upward propagation associated with energy leakage, and the normal modes also have significant imaginary amplitudes in the atmosphere. Due to its smaller size and to a low resonance frequency (associated with the cold atmospheric temperature), this transition for Mars is found at $\ell = 8$, while it is observed for $\ell = 28$ and 22 for the Earth and Venus, respectively. The amplitudes are also proportional to the ratio of acoustic impedance between the ground and atmosphere.

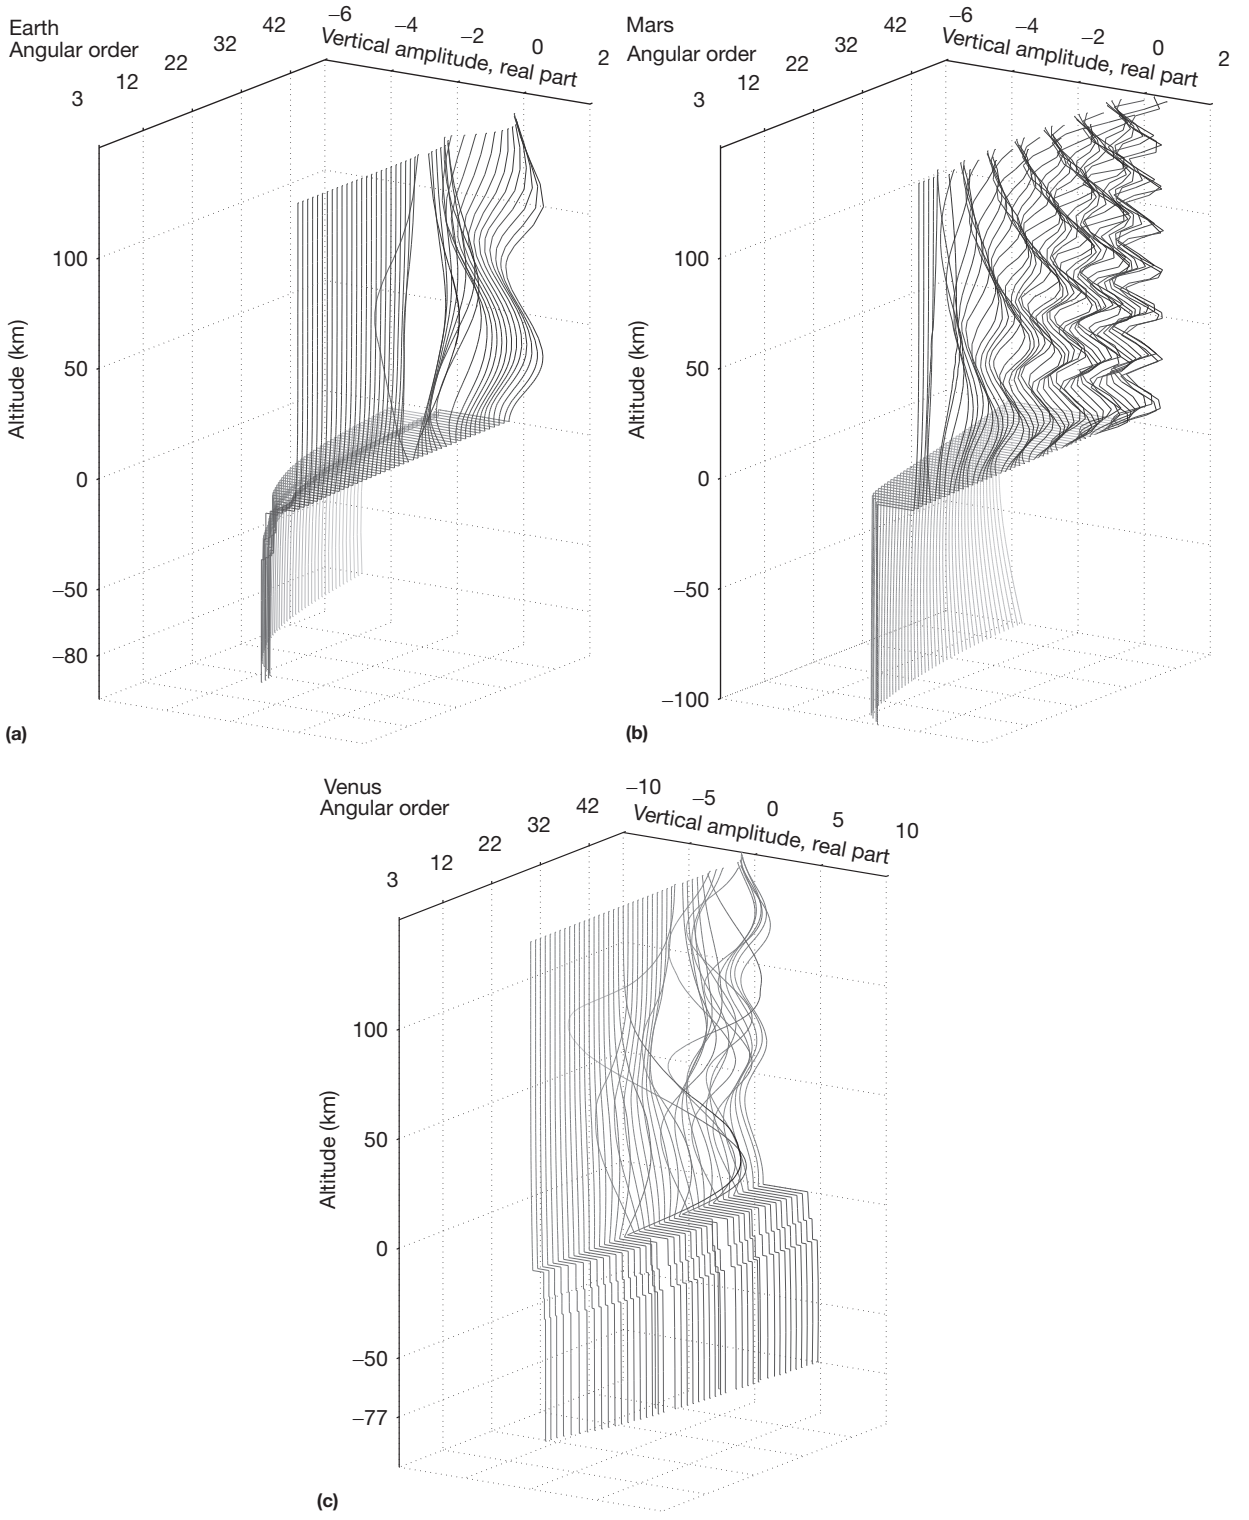

Figure 20 Rayleigh normal modes for Earth (a), Mars (b), and Venus (c). The amplitudes shown are the vertical displacement multiplied by the square root of density. Amplitudes are multiplied by 5 for the Earth and by 50 for Mars. For Venus, amplitudes are not amplified. Amplitudes are shown over a vertical scale from a depth of 100 km to an altitude of 150 km. Note that, in all cases, the amplitudes decay exponentially when close to the surface for the low angular orders below the cutoff frequency, with the single oscillation at the resonance comparable to the amplitude of the atmospheric fundamental modes and the oscillating amplitudes above the resonance frequency.

10.03.4.2 Mars Hum and Martian Atmospheric Sources

We now address the possibility of the continuous excitation of normal modes by the martian atmosphere. Kobayashi and Nishida (1998) originally proposed amplitudes on Mars to be a factor of 2–3 smaller than those on Earth, while amplitudes on Venus were expected to be comparable with Earth amplitudes. These early studies primarily considered excitation by turbulence in the boundary layer, however. (See more on the theory and assumptions in Tanimoto (1999, 2001).) This theory was later criticized by Webb (2007), who showed that it yields an overestimation of the normal mode amplitudes by several orders of magnitude.

Can we still imagine that normal modes might be excited with potentially observable amplitudes? Instead of turbulence, let us consider nonturbulent large-scale winds and atmospheric circulation. As they generate wind Reynolds stresses, they act as a potential seismic source. As shown by Lognonné et al. (1994), the density of pressure glut can then be expressed as

$$m_{ij} = \left(p + \kappa \nabla \cdot \vec{u}\right)\delta_{ij} + \rho v_i v_j \qquad [12]$$

where p is the atmospheric pressure, v_i is the ith wind velocity component, ρ is the density, κ is the bulk modulus of the atmosphere, and $\vec{u}$ is the displacement field of the normal modes in the atmosphere. In the isotropic case, when wind is neglected, the pressure is much greater than the Hook pressure of normal modes, and we have $m_{ij} = p d_{ij}$. The amplitude of a normal mode with angular order ℓ and eigenfrequency ω_ℓ can then be expressed with a similar formalism, as in Lognonné et al. (1994), which leads to

$$a_\ell^m(t) = \int_{-\infty}^{t} \mathrm{d}\tau \, \mathrm{e}^{\mathrm{i}\omega_\ell(t-\tau)} \iint \mathrm{d}\Sigma \, \overline{Y}_\ell^m(\theta, \phi) \int_0^{+\infty} \mathrm{d}z A_\ell(z) \frac{Mp(z, \theta, \phi, t)}{R\rho_0(z)} \qquad [13]$$

where z, θ, ϕ are the altitude, latitude, and longitude, respectively; $a_\ell^m(t)$ is the acceleration of a given normal mode at a time t; $A_\ell(Z)$ is an excitation term that depends on the atmospheric-solid planet coupling, related to the divergence of the normal-mode eigenfunction times, the amplitude of the mode on the recording direction; $\overline{Y}_\ell^m$ is the complex conjugate of spherical harmonic of degree ℓ and order m; p is the atmospheric pressure; R is the thermodynamical constant; ρ_0 is the atmospheric density; and M is the mean atmospheric molar mass (Note that $Mp/R\rho_0$ has the dimension of temperature.). Values of the excitation terms, $A_\ell(Z)$, at the surface of the planets (z=0), are shown in **Figure 21** for the fundamental normal modes of Earth and Mars. On Earth, at an angular order up to 28 or 29, acoustic energy is trapped and therefore not radiated. On the other hand, acoustic trapping on Mars occurs at an angular order below 10 for all realistic atmospheric models, leading to a dynamic coupling of the planet's normal modes and atmospheric circulation that is quite efficient for low-order angular modes. Thus, the coupling coefficient for Mars is comparable to the coefficient for Earth at angular orders of about 10, but, as a consequence of the lower atmospheric density on Mars, it is typically a factor of 10 smaller than Earth's coupling coefficient for angular orders >20. Temperature fluctuations and winds are significantly larger on Mars, however.

Global circulation models (Forget et al., 1999) can be used to obtain more precise estimates of the continuous excitation of normal modes through a computation of the pressure glut. **Figure 22** shows the right-hand side of eqn [13], which corresponds to the excitation term related to the pressure field at a given local time and for a classical global circulation model (GCM) just before time-integration and multiplication by $\mathrm{e}^{\mathrm{i}\omega_\ell(t-\tau)}$. Large excitations are observed in this model, including excitations along atmospheric fronts in the southern hemisphere. After time-integration, such models provide the

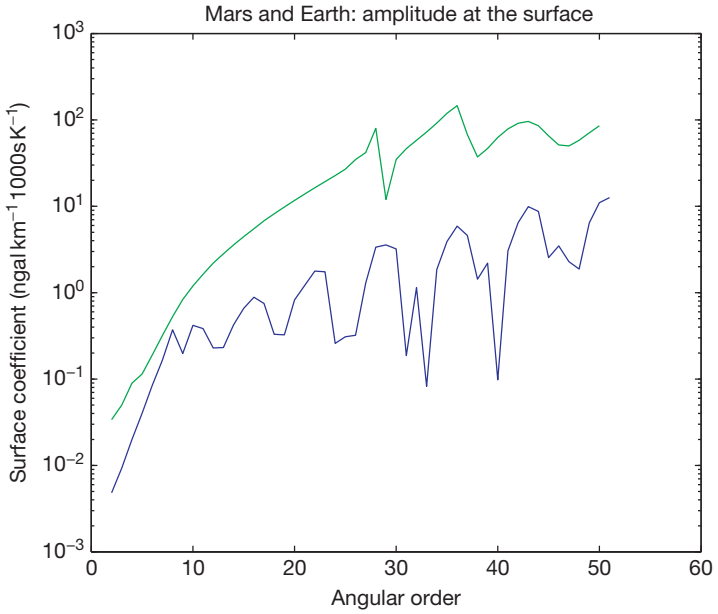

Figure 21 Excitation term $A_\ell(Z)$ versus angular order for Earth and Mars (eqn [13]) at the surface of the planet (z=0). Note that, at low angular order, the excitation terms for the two planets are comparable. Due to the high temperature variations, the martian hum might therefore be more efficient for these low order terms than on Earth.

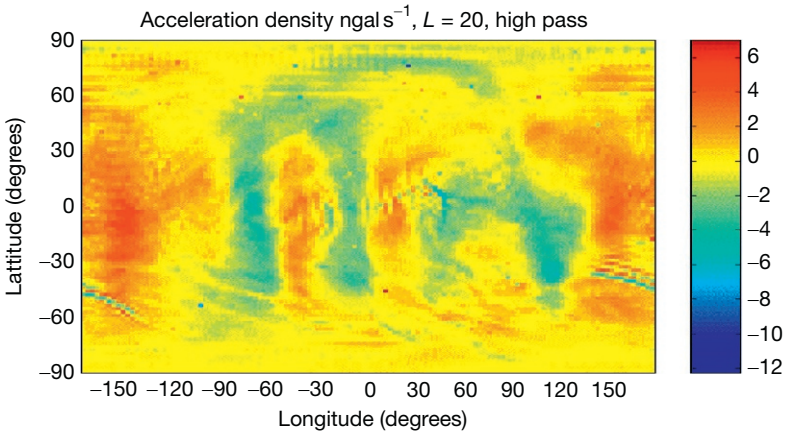

Figure 22 Acceleration field of a martian GCM model at a given time on the planet, obtained for a 30-day run of the GCM (Forget et al., 1999), corresponding to the term $a_\ell^m(t)$ in eqn [13]. The field is computed for the spheroidal mode ${}_0S_{20}$ and includes the vertical, last integration of eqn [13], but not the Legendre transformation or the time integration. Note the presence of the atmospheric front in the southern hemisphere, which provides highly localized excitation of the normal modes, as well as the large-scale pressure field associated with the daily variation.

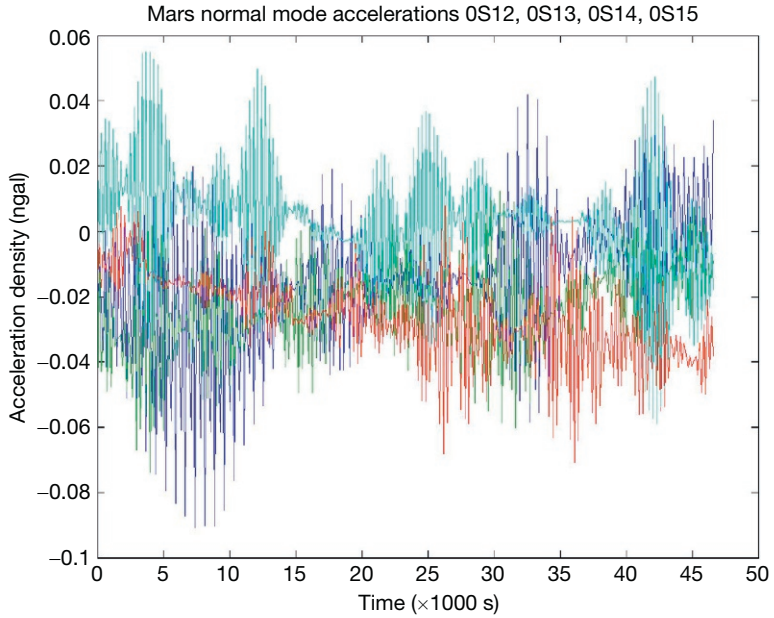

Figure 23 Simulations of the permanent excitation of normal modes for the spheroidal modes ${}_0S_{12–15}$ on Mars, with a GCM model, during a 2-week period. An interval of about 14 h is shown, illustrating the typical amplitude variations for these modes, with typical periods from 400 to 300 s. Increasing angular orders are coded blue, green, red, and cyan, respectively. Observed amplitudes on Earth below an angular order of 20 are 0.2 ngals.

acceleration amplitudes of the modes (Figure 23). As mentioned above, these estimates probably represent minimum values, because GCMs do not model short-scale circulations in the atmospheric boundary layer. Yet, the results still show that a small excitation is achieved by atmospheric global circulation. Moreover, the global circulation on Mars is more coherent than the circulation on Earth from one day to the next. So, if long-duration measurements become available, increasing signal strength through stacking methods may be possible. Even though the search for continuous excitations will be challenging, due to the extremely low amplitudes and the high noise associated with the surface installation of seismometers on Mars, it can open exciting opportunities for the detection of low-angular-order normal modes, and it will benefit from long-lived seismic monitoring and the stacking methods that monitoring would enable.

We now briefly consider the effect of the atmosphere over shorter periods. Atmospheric wind-induced turbulences are known to be a source of SP seismic noise in the frequency range of 0.1–10 Hz (e.g., Steeples et al., 1997). Recent studies in terrestrial seismology using cross-correlation techniques have shown that the shallow and middle crust can be imaged by extracting Green's function for Rayliegh waves from long sequences of ambient seismic noise generated by atmospheric sources. The same technique has been employed on the Moon at much shorter periods, using thermally generated noise, for

the investigation of the near-subsurface (Larose et al., 2005; Sens-Schönfelder and Larose, 2010; Tanimoto et al., 2008). Such a technique was also applied in California on short period (6–20 s) surface waves (Shapiro and Campillo, 2004; Shapiro et al., 2005), and the technique can be applied to shorter-wavelength surface waves as well, as it is sensitive to the uppermost kilometers of the crust. Martian atmospheric turbulence, especially the localized dust devils, can probably generate surface waves comparable to the waves generated on Earth. Passive short period surface wave observations, possibly from multiple sensors, may provide an alternative to future active seismic experiments for studying the martian subsurface and the associated water reservoirs. This would obviate the technological and safety challenge of carrying explosive seismic sources to Mars, as was done on the Moon for the Apollo seismic experiments.

10.03.4.3 Venus Atmospheric Seismology

As noted earlier, ionospheric disturbances associated with acoustic waves generated by Rayleigh surface waves have been observed in connection with very large ($M_w > 7$) earthquakes (e.g., Artru et al., 2004; Ducic et al., 2003; Garcia et al., 2005a), as well as earthquakes of lesser magnitude. Calais and Minster (1995) reported ionospheric perturbations on GPS data following the Northridge ($M_w = 6.7$) earthquake, and observations have demonstrated the acoustic-coupling effects of earthquakes with magnitudes as low as 5.9, with reported thermospheric perturbations of about 300 K between 300 and 400 km of altitude (Kelley et al., 1985). For a short review of ionospheric postseismic perturbation, see Lognonné et al. (2006). The detection of atmospheric signals associated with quakes might therefore be an interesting alternative to seismometer use, especially if measurements can be performed by orbiting spacecraft or Earth-based telescopes. However, Venus is the only planet where possibly weaker seismic activity is counterbalanced by stronger atmospheric coupling, enabling seismic studies using this alternative strategy.

Despite claims of microseismic signal detection during the operational life of the Venera landers (Ksanfomaliti et al., 1982), the establishment of a long-term seismic station on Venus will be a huge challenge (Stofan et al., 1993), and an orbit-based seismic pathfinder survey is therefore an elegant, low-cost option. We can estimate the amplitude of the atmospheric signals expected to accompany large quakes on Venus. The amplitudes of seismic waves in the Venusian atmosphere are related to the acoustic jump at the surface and the associated transmission coefficient, as well as to altitude-related amplification. At the Venusian surface, the atmospheric pressure is about 90 bars, the density is about 65 kg m^{-3}, acoustic velocities are slightly higher (425 m s^{-1}) than Earth velocities, and ground coupling (ρc) is about 60 times greater. At an altitude of 50 km in Venus' atmosphere, the pressure is comparable to Earth's surface pressure, but the density is almost two orders of magnitude lower than the density at the Venusian surface. These two effects mean that, for a given altitude and quake moment magnitude, atmospheric signals are expected to be about 600 times greater on Venus than on Earth, making orbit-based detection a viable possibility.

The first possibly detectable signal might be the atmospheric and ionospheric perturbation in the vicinity of a Venusian quake. Such a signal will consist of a plume that generates temperature and possibly brightness-albedo, as well as atmospheric–ionospheric oscillations. The near-source characteristics of a generated acoustic plume were first studied by Garcia et al. (2005b), who showed that either adiabatic oscillations corresponding to the acoustic waves or nonadiabatic deposition could be generated. For $M_w = 6$, adiabatic temperature oscillations of about 100 K and postseismic heating of about 10 K were also found (**Figure 24**). These perturbations take place very close to the source, however, within a distance comparable to the event depth, and the observation of such effects will therefore require a global, high-resolution survey that might only be achieved by spacecraft near Venus. The detection of signals related to an acoustic plume was attempted with the Virtis experiment (Drossart et al., 2004), onboard the European Space Agency's (ESA) Venus Express spacecraft, in orbit around Venus without success.

In addition to these signals in the vicinity of the quakes, infrasound and surface waves generated by the quake will also produce atmospheric signals, which can be detected at larger distances. These waves can be computed more precisely using the theory developed by Lognonné et al. (1998b), and, in the cases of both Earth and Venus, the differences in atmospheric coupling can be analyzed via the spherical PREM (Dziewonski and Anderson, 1981), with Venus' interior pressures employed in the PREM applied to that planet.

A first, impressive effect of atmospheric coupling is the strong perturbation of the quality factor of the interior's fundamental normal modes (**Figure 25**). The presence of the atmosphere decreases the attenuation coefficient of Rayleigh modes, Q, due to the escape of energy. For Earth, this effect is comparable to or smaller than the error in the determination of Q. For example, the Earth normal mode ${}_0S_{98}$ is close to 10 mHz and has a Q of 115 with the atmosphere and a Q of 118 without the atmosphere, implying an atmosphere-related Q-decrease of only 2.5%. On Venus, we get a Q of 108 for the mode ${}_0S_{93}$ with the atmosphere and a Q of 121 without the atmosphere, corresponding to a decrease of more than 10%. The difference in atmosphere-related Q-decreases means that about 10% of the energy of the Rayleigh waves is dissipated in the Venus atmosphere, confirming the importance of the coupling that occurs in it.

A comparison of synthetic seismograms for the two planets allows further examination of coupling effects. **Figure 26** shows the atmospheric oscillations for Earth and Venus at a 150-km altitude for the same epicentral distance and seismic source. We find amplitudes about 100 times larger on Venus than on Earth, reaching 0.3 m s^{-1} at these periods and corresponding to wavelengths longer than 300 km. Amplitudes will be about one order of magnitude larger at 20 s but are much smaller, of course, for low-order angular modes. **Figure 27** shows the amplitude for the fundamental Rayleigh mode in the latter case, as well as for the fundamental and two first overtones of the atmospheric waveguide. For a quake releasing a moment of 10^{18} Nm, we get individual mode amplitudes of a few cm s^{-1} at 150-km altitude and angular orders >30. At 120 km, however, amplitudes do not reach 1 mm s^{-1}.

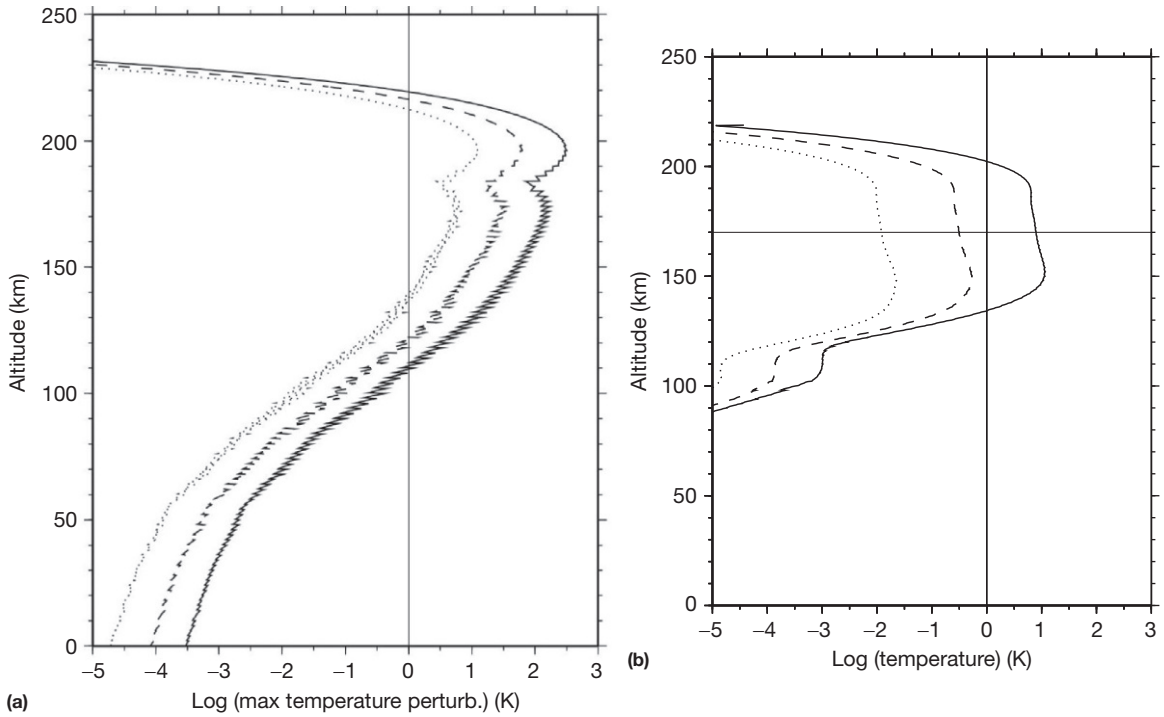

Figure 24 Logarithm of (a) the maximum adiabatic temperature perturbation (in K), as a function of altitude (in km) for earthquake moment magnitudes $M_w = 5$ (dotted line), $M_w = 5.5$ (dashed line), and $M_w = 6$ (plain line). In (a), the signals have periods corresponding to the acoustic waves, and the vertical bar represents a 1-K amplitude. In (b), the figure is the same but for the nonadiabatic heating associated with acoustic energy deposition in the atmosphere, which remains for a longer time before atmospheric thermal diffusion. The additional horizontal line represents the minimum altitude at which the signal is maintained for more than 200 s. At higher altitudes, the temperature anomalies remain for about 4 min. Reprinted from Garcia R, Lognonné P, and Bonnin X (2005) Detecting atmospheric perturbations produced by Venus quakes. *Geophysical Research Letters* 32: L16205; Garcia R, Crespon F, Ducic V, and Lognonné P (2005) 3D ionospheric tomography of post-seismic perturbations produced by the Denali earthquake from GPS data. *Geophysical Journal International* 163: 1049–1064, with permission of the Geophysical Research Letters.

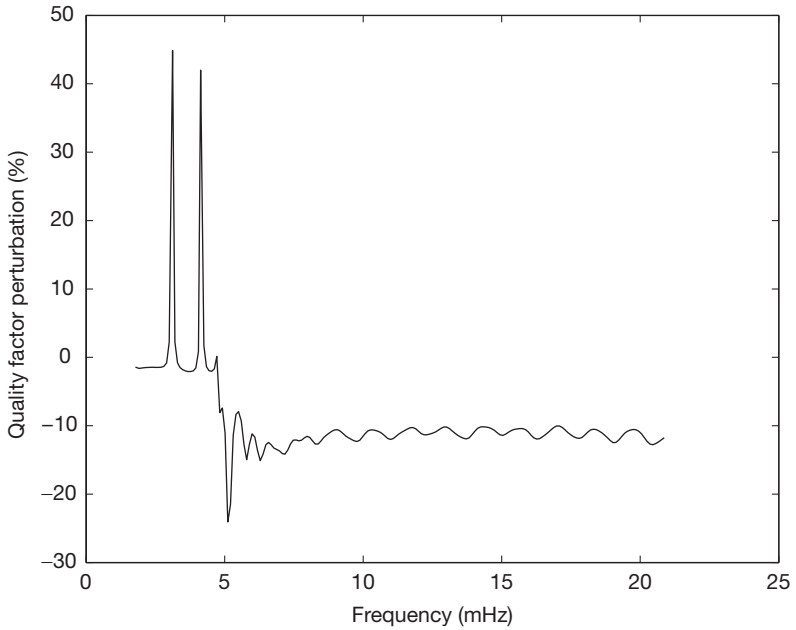

Figure 25 Perturbation of the quality factor for the spheroidal fundamental normal modes. The two peaks are associated with resonances at which significant energy is transferred into the atmosphere, instead of within the solid planet. At these two frequencies, the surface waves have a significant part of their energy in the atmosphere, where attenuation processes are smaller than the attenuation processes in the solid part of the planet. This distribution of wave energy leads to reduced attenuation. The resonance is related to the crossing of the Rayleigh dispersion branch with the fundamental acoustic branch. For the other frequencies, and especially those larger than 5 mHz, modes lose a significant fraction of their energy in the atmosphere, as all the energy transferred across the solid-atmosphere discontinuity propagates upward and dissipates at high altitudes through viscous and nonlinear processes.

Figure 26 LP vertical atmospheric oscillations for a 10^{18} Nm quake ($M_w = 5.9$) and for a period longer than 100 s on Venus (a) and on Earth (b). Due to the difference in the acoustic coupling at the ground, at an altitude of 150 km, ionospheric signals on Venus are about 100 times stronger than the signals produced by an earthquake of the same magnitude. This is about 1.3 M_w magnitude. Ionospheric velocity oscillations are about 0.3 m s^{-1} peak-to-peak at these periods, corresponding to wavelengths larger than 300 km. Thus, they will be about one order of magnitude larger at 20 s.

The presence of seismic signals in the Venus atmosphere open the possibilities of remote detection, either from Earth or from Venus orbit. This type of detection can be accomplished using remote sensing techniques of the neutral atmosphere, as done in Jupiter seismology (see **Section 10.03.4.4** below), or by way of ionospheric sounding, as done in Earth ionospheric seismology (e.g., Lognonné, 2009). In regards to neutral-atmosphere remote sensing, the detection of oscillations

Figure 27 Free oscillation amplitudes (vertical velocities in m s^{-1}), with respect to angular orders, for a quake with a seismic moment of 10^{18} Nm ($M_w = 5.9$). All amplitudes are expected to be multiplied by the spherical harmonics values at the locations of their respective observations. Sky blue stars represent the Rayleigh fundamental modes. Dark blue circles represent the fundamental acoustic modes. The green × and red + represent the first and second acoustic modes, respectively. For angular orders below 20, the order of the branches is as follows: Rayleigh fundamental modes, fundamental mode, first acoustic overtones, second acoustic overtones. In the intraplate-cooling hypothesis, such quakes are expected at a rate of 2 per month (quakes with moments and therefore amplitudes ten times larger are expected at a rate of 5 per year). The top left figure shows the amplitudes of the modes at an altitude of 120 km (which can be sounded by optical-imaging systems), while the top right figure shows the amplitudes at an altitude of 150 km (which can be achieved by Doppler sounder). The two bottom figures show the frequencies and quality coefficient of the modes. As no viscosity is taken into account in the model, the Q values for the fundamental and first acoustic modes are high. The Q of the second overtone is much lower because of the partial trapping of the modes, while the Q of the Rayleigh modes is also low due to attenuation in the solid part.

below 120 km does not seem feasible, however. Jupiter normal oscillations do remain coherent for very long times, because of their very high quality coefficient, but on Venus oscillations have a very low Q, typically 200 for periods of 200 s. As a result, the tools used in Jovian seismology, with typical detection threshold in the range of 0.5–1 m s^{-1}, are not sensitive enough to detect atmospheric osciallations on Venus. Amplitudes at higher altitudes of the Venus atmosphere might be detectable with ionospheric sounders, however. The Venus ionospheric structure is indeed thinner, and maximum ionization is found at about 150 km. A sounding from the top is therefore possible at such an altitude, contrary to the sounding situation for Earth, where maximum ionization occurs at about 300–350 km, preventing access from the top of the ionospheric layers between 150 and 200 km altitude. On Venus, electron density ranges from 5×10^3 cm^{-3} to 15×10^3 cm^{-3} during the night and from 5×10^5 cm^{-3} to 5×10^5 cm^{-3} during the day, producing electron plasma frequencies ranging from 0.5–1.5 MHz during the night to 3–7 MHz during the day. A Doppler sounder, with performances below 1 cm s^{-1} in Doppler measurement (Artru et al., 2004), might then offer exciting perspectives for remote sensing seismology on Venus and has to be considered for placement on a future, high-altitude Venus orbiter.

10.03.4.4 Giant Planets Seismology

As is the case with the telluric planets, the internal structure of the giant planets is weakly constrained by geophysical data, and their seismology could provide important new data regarding their structure and dynamics. For a review on the giant planets' internal structures, see Guillot (2005).

We briefly review the main seismological properties of giant planets, before describing the current state-of-the-art techniques for observing these bodies. For a more complete review, including early observations, see Lognonné and Mosser (1993) and Mosser (1995). In contrast to telluric planets, the mantle and possibly even the rocky core of a giant planet are fluid (Guillot, 2005), meaning that only acoustic and gravity waves can be detected. Moreover, the waves are not trapped by a solid-atmospheric discontinuity but rather by the effect of atmospheric density decay, and therefore, the waves are reflected backward only when their frequency is smaller than a frequency called the atmospheric cutoff frequency, which depends on atmospheric structure. Only waves with frequencies lower than the atmospheric cutoff frequency are reflected back into the interior and can therefore generate surface waves or normal modes with high-quality coefficients. In contrast, waves with higher frequencies will continue upward and will be transient, before being dissipated at high altitude.

Figure 28 shows the sound speed and density structure for two typical Jovian interior models, with and without a plasma phase transition (PPT). At this transition, molecular hydrogen is dissociated into metallic or plasma hydrogen (e.g., Saumon and Chabrier, 1989; Saumon et al., 1992). For Jupiter, the cutoff frequency, also shown on **Figure 28**, reaches a maximum of about 4.5 mHz for 50 km above the one-bar level and then decreases to about 3.3 mHz, a stable value achieved between 100 and 200 km of altitude. Low-attenuation normal modes can therefore be found only below 3.3 mHz, while leaky modes can exist between 3.3 and 4.5 mHz. No surface waves exist at frequencies higher than the maximum value of the cutoff frequency; a detailed description of the propagation of seismic waves in the Jovian troposphere and stratosphere can be found in Mosser (1995).

The theoretical spectrum of free Jovian oscillations was computed for models of Jupiter in the late 1970s (Vorontsov and Zharkov, 1981; Vorontsov et al., 1976). As with the Earth and other planets, these theoretical studies, as well as more recent ones (Gudkova and Zharkov, 1997, 1998), including studies of giant exoplanets (Le Bihan and Burrows, 2013), have shown free oscillation frequencies that are highly sensitive to internal structure. As noted earlier, on Jupiter, free oscillations with frequencies higher than about 3 mHz are not trapped. **Figure 29** shows the spectrum of free oscillations for the Jupiter model without PPT, which is shown in **Figure 28**. Only a bulk Q of 10^6 was considered and the viscosity was neglected. As a result, the low Q-values found for frequencies higher than 3 mHz are due mainly to the nontrapping of the waves. Note that the fundamental mode is, in fact, a gravity mode and that the first acoustic mode is for $n=1$ (Lognonné et al., 1994). **Figure 30** shows the amplitudes of the modes, scaled by the square root of the density. Note the trapping of the modes below the cutoff frequency again and the oscillating characters of the acoustic $n=1$ mode for frequencies higher than the cutoff frequency.

The search for the free oscillations of Jupiter started in the late 1980s, with the first successful detection achieved 30 years later (Gaulme et al., 2011). Several techniques were used, including infrared observations (Deming et al., 1989),

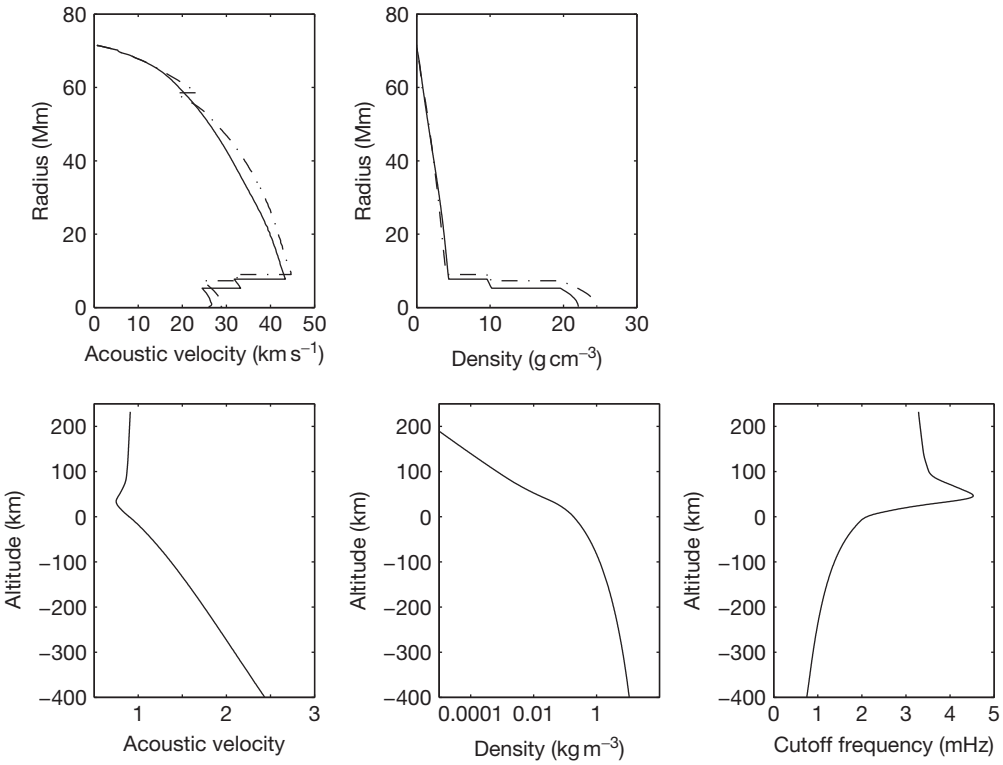

Figure 28 Seismic properties for two different models of Jupiter (Mosser, 1996). The continuous line represents a model without plasma phase transition (PPT) discontinuity, while the dashed line represents a model with a PPT. The two upper figures refer to the entire planet, while the three bottom ones pertain to the atmosphere, displaying the acoustic velocity, the density, and the cutoff frequency, respectively.

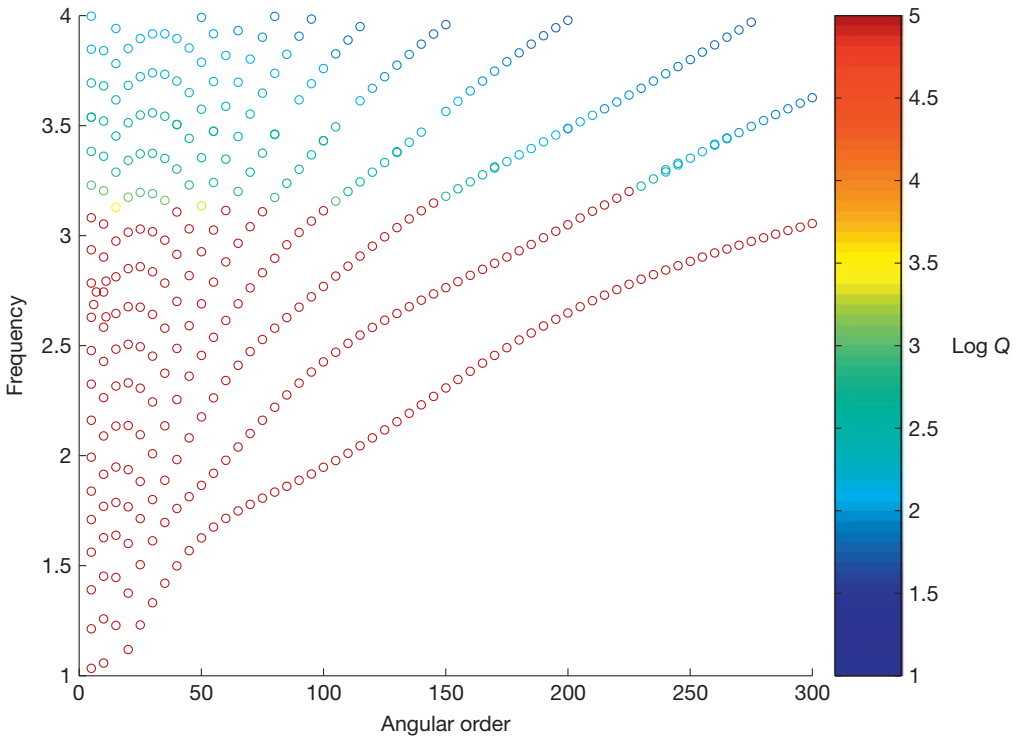

Figure 29 Dispersion curves of the Jovian normal modes for a model of the interior without PPT. Modes are shown with L values increasing by 5 from 5 to 300. The color represents the decimal logarithm of the Q value. Note that Q strongly decreases for frequencies higher than 3 mHz as a consequence of the lack of trapping. The tropospheric guided modes, at about 3.50 mHz, are not shown in the figure.

Doppler spectrometry observations (Cacciani et al., 2001; Mosser et al., 1991; Schmider et al., 1991), Fourier transform interferometry (Mosser et al., 1993, 2000), albedo modulation (Lederer et al., 1995) and Mach–Zender interferometry (Gaulme et al., 2011; Schmider et al., 2003, 2007). This last technique led to the first successful observation of normal mode signatures (Gaulme et al., 2011). Although the latter has not yet resulted in the determination of the frequencies of normal-mode multiplets, several features have been isolated that are associated with low-order modes ($\ell \leq 0-3$). The first is a clear excess of power (over noise) in two detection bands: 0.8–2.1 and 2.4–3.4 mHz. The associated amplitude of normal modes is about 50 cm s^{-1}. This is about twice the detection level of Schmider et al. (1991) and Mosser et al. (1993), who first detected the excess signal over the noise in the frequency band 0.5–1.8 mHz. More importantly, the signal was clearly detected in an Echelon diagram of a periodicity of 155.3 ± 2.2 μHz (An Echelon diagram is the spectrum of an amplitude spectrum and is therefore a tool to detect the relatively regular spacing between normal modes with the same angular order but increasing radial orders). **Figure 30(a)** shows such frequency spacing between modes with increasing radial numbers but the same angular order, suggesting that the detected modes (located in the green box) have radial orders in the range of 5–10.

If these observations do not yet have the precision required for strong constraints on the Jovian interior structure, initial constraints can still be placed on the excitation processes. By using the excitation kernel of normal modes to pressure glut (Lognonné et al., 1994), we can indeed suggest excitations in the 10–10^3-bar level (**Figure 30(b)**), where significant convection is expected to occur. More detailed analysis of these observations will likely be an important part of future Jovian research activities (e.g., Jackiewicz et al., 2012), and we hope that continuous observation will also reduce the detection threshold by an order of magnitude after 1 month, then reaching a limit of about 10 cm s^{-1} and enabling the precise determination of normal-mode frequencies on Jupiter.

As noted earlier, body waves cannot be trapped in the atmosphere, but, in principle, these waves can be excited by a localized source. Due to the large energies involved, the impact of the Shoemaker–Levy 9 comet was such an event. In that case, signal amplitudes were theoretically predicted for different impactor masses (Kanamori, 1993; Lognonné et al., 1994; Marley, 1994). For an impact with an energy $> 10^{21}$ J, peak-to-peak temperature fluctuations greater than ~0.01 K were expected for 10-mHz frequency P waves, while surface waves below 3 mHz were expected to generate fluctuations in excess of 0.01 K for impacts $> 2 \times 10^{21}$ J (Lognonné et al., 1994). No observations were reported by Mosser et al. (1996) for impacts A and H, nor by Walter et al. (1996) for impact R, resulting in upper limits on the impact energy of $1–2 \times 10^{21}$ J. Though the impact did not generate detectable body waves, it did produce a ring-like pattern in the Jovian atmosphere, with two rings propagating at 210 and 450 m s^{-1} (Hammel et al., 1995). If such a wave is neither an acoustic body wave nor a surface wave, it is probably a gravity wave, propagating either in the stratosphere (Walterscheid et al., 2000) or in a deeper layer. In the latter case, an enhancement of the water content by a factor of 10 at a depth of 10 bars (about 80 km below the 1 bar level)

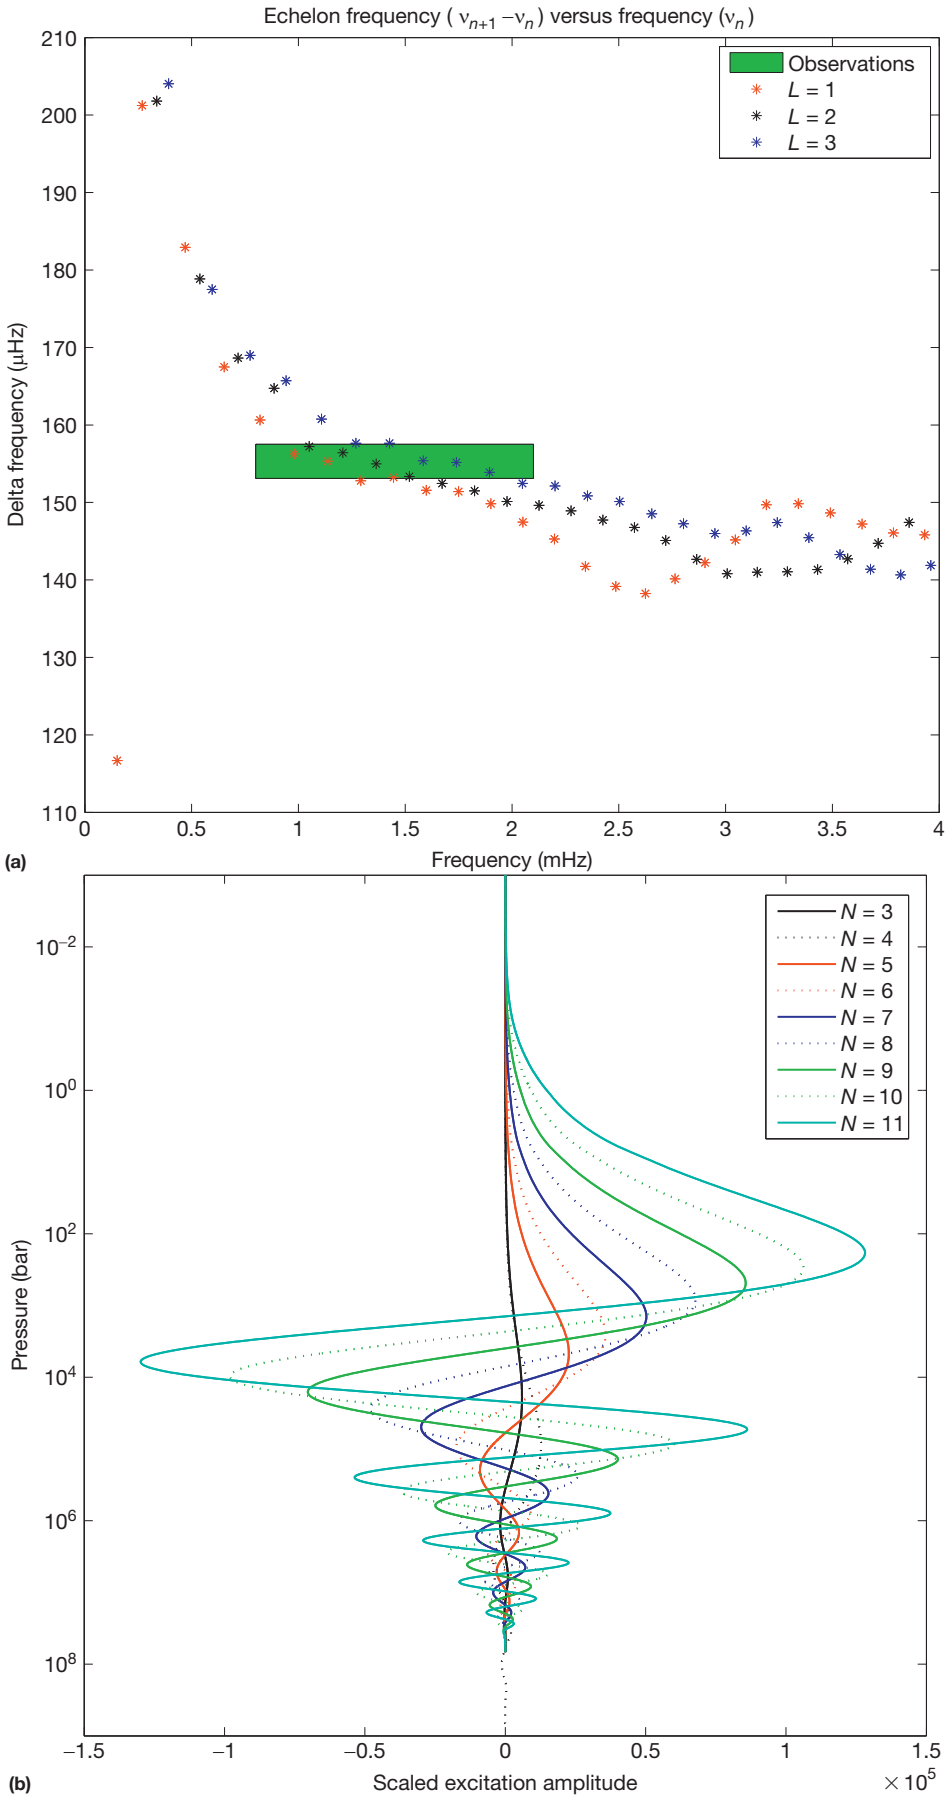

Figure 30 (a) Frequency spacing between two consecutive normal modes for low angular orders $L = 1$, 2, 3, as a function of the normal mode frequency. The green rectangle indicates the periodicity detected by Gaulme et al., 2011. The normal modes start at low frequency with the fundamental mode. (b) Excitation kernel of the $L = 2$ fundamental mode and harmonics, as a function of pressure. The excitation kernel is $\mathbf{u}_{p\_obs}$ $(\mathrm{div}\mathbf{u})_{p\_ex}$, and an observation depth of 1 bar is assumed. These kernels show large amplitudes in the range of 10–1000 bar.

is necessary to explain the wave speed (Ingersoll and Kanamori, 1995; Ingersoll et al., 1994). See Kanamori (2004) for a detailed discussion of this wave.

10.03.5 The New Step: Mars Seismology

We now return to the inner solar system, specifically to martian seismology. In the previous section, we showed that the indirect seismological exploration of Mars may be possible (but very challenging) through the study of the continuous excitation of normal modes by the martian atmosphere. Here we revisit traditional, quake-based seismology, motivated by the InSight Discovery mission, which will deploy a geophysical station on Mars in September 2016 (Banerdt et al., 2012, 2013). InSight will be the first step in almost two decades toward establishing extraterrestrial seismic networks (see, e.g., Lognonné et al., 1996, and for complete list of project references, Lognonné, 2005). A seismic network on Mars would contribute enormously to our understanding of Mars as a planet, and in our opinion, network placement should be one of the highest priorities for the 2020+ exploration of Mars, as illustrated recently by Mocquet et al. (2011) or Dehant et al. (2012).

Given the lack of quake detection by the Viking landers (Anderson et al., 1977a,b) and the failure of the Mars96 mission, which included seismometers on two small autonomous stations and two penetrators, very little is known regarding the seismic properties of Mars. Thus, InSight will provide our next opportunity to directly build our understanding of martian seismology. The mission has been designed with a priori constraints on seismic models that we will review briefly in this section. We then close the section by considering topics relevant to operating a network with a relatively small number (e.g., 2–5) of seismic stations, which is a logical post-InSight next step in Mars' exploration.

10.03.5.1 Interior Structure of Mars

Since the Viking mission, several authors have proposed seismic and density models of Mars. The two main types of constraints used for such models are geophysical and geochemical. Geophysical constraints include the mean density of the planet, which is obtained from the planetary mass (M) and the mean planetary radius (a); the mean moment of inertia factor (I) or the moment of inertia with respect to the rotation axis (C); and the k_2 Love number, which is associated with the gravity signal generated by the Sun tide. Okal and Anderson (1978) proposed a model based on the PREM, with a core size adjusted to fit only the mean density. In this model (and similarly for other models) the pressure range in the entire martian mantle corresponds to the pressure range in Earth's upper mantle.

A second set of geochemical constraints is inferred from the planet's possible bulk composition, which is based on analyses of martian meteorite composition. One of the most-used models, proposed by Dreibus and Wänke (1985), assumes that the bulk silicate composition of Mars is a mixture of carbonaceous C1 chondrite material and volatile-depleted C1 material, with a Mars crustal composition constrained by the SNC group of martian meteorites. Other model mixtures have been proposed, in order to match the $\delta^{17}O/\delta^{18}O$ ratio: a 55% ordinary chondrite H and 45% enstatite chondrite EH (Sanloup et al., 1999), or a 85% H chondrite, 11% CV chondrite, and 4% C1 chondrite (Lodders, 2000; Lodders and Fegley, 1997). One of the important features of these models is the iron enrichment in the mantle (around twice the Earth's value). As illustrated by Mocquet et al. (1996), the presence and depth of seismic discontinuities in the Mars mantle is likely related to the iron content if the mantle is olivine rich (about 60% in volume). A pyroxene-rich mantle (e.g., Sanloup et al., 1999) should display different discontinuities with smaller amplitudes of the seismic jumps (Verhoeven et al., 2005).

Several models have produced revised estimates of the inertia factor, as compared with the factor provided by Sohl and Spohn (1997) and Zharkov and Gudkova (2000), who used a value of $C = 0.365\ \mathrm{Ma}^2$, corrected for the nonhydrostatic contribution of the Tharsis bulge (Kaula, 1979). This value is close to the value later obtained from the measurement of the precession rate of the planet by the Pathfinder mission ($C = (0.3662 \pm 0.0017)\mathrm{Ma}^2$, Folkner et al., 1997).

The new inversions performed during the last decade have found slightly lower value for C, while reducing the error by almost three, using the data collected by the Mars Global Surveyor, MRO, and Odyssey orbiter. $(C/(MR_e^2) = 0.3650 \pm 0.0012$ where R_e is the equatorial radius, Yoder et al., 2003 and $C/(MR_e^2) = 0.3644 \pm 0.0005$ for the most recent determination of Konopliv et al., 2011). All these values should be corrected by the perturbation of the gravitational oblateness J_2 (Munk and MacDonald, 1975) and the one of the J_{22} term (Sohl et al., 2005) in order to get the mean moment of inertia:

$$I = C - \frac{2}{3}J_2\mathrm{Ma}^2 - \frac{8}{3}J_{22}\mathrm{Ma}^2 \qquad [14]$$

These corrections reduce the C value by $1.30e-3$ and $1.68e-4$, respectively (Sohl et al., 2005), leading to $C = (0.3645 \pm 0.0005)\mathrm{Ma}^2$.

The other geophysical datum measured to date is the Love number k_2, obtained from gravity analysis of orbiting spacecraft. This value is poorly known, however. If, following Yoder et al. (2003), Bills et al. (2005), and Konopliv et al. (2011), the value of k_2 is about 0.16 or larger (e.g., 0.164 ± 0.009, Konopliv et al., 2011), then only models with a large core radius (1630–1800 km) are possible (**Figure 31**), as shown by van Hoolst et al. (2003), in contrast to models inferred from the earlier k_2 estimates in the range 0.10–0.13 (Balmino et al., 2005; Marty et al., 2009; Smith et al., 2003). In general, these data support iron cores with some light element(s). In addition to sulfur (e.g., Dreibus and Wänke, 1985), proposed light elements include hydrogen (Gudkova and Zharkov, 2004), silicon (Sanloup et al., 2002; Stevenson, 2001), and carbon (Kuramoto, 1997), while oxygen, another light element possibly present in the Earth's core, is less likely on Mars (Rubie et al., 2004). Differences might, however, be large enough in term of planetary evolution. As an example, the presence of a perovskite-bearing lower mantle becomes impossible for a core larger than 1500 km in radius (e.g., Wang et al., 2013a,b for a recent study), due to insufficient pressures in the mantle, but a larger core radius cannot be ruled out for hot mantle models 4 billion years ago

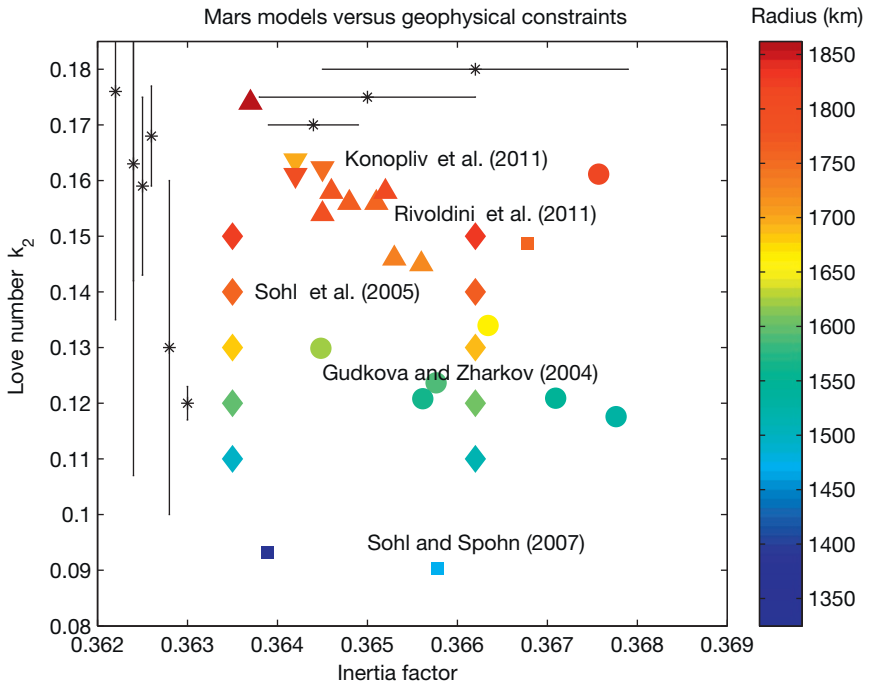

Figure 31 Computed k_2 and inertia factors for the early models of Sohl and Spohn (1997) (squares), Gudkova and Zharkov (2004) (circles), and Sohl et al. (2005) (diamonds) among others, as well as the models produced by Konopliv et al. (2011) (inverted triangle) and Rivoldini et al. (2011) (triangle). This figure illustrates the narrowing zone of the acceptable models resulting from improvements in inertia factor measurement and, to a lesser extent, improvements in k_2 Love number measurement. The inertia factor measurements, located at the top of the figure, are given with their error bar, and from top to bottom, the measurements accredited to Folkner et al. (1997), Yoder et al. (2003), and Konopliv et al. (2011). The measurements for the Love number k_2 are in the left, and they are arranged from left to right, with two types of results displayed. Those measurements in the top converge toward a value of about 0.16 and are reported by Bills et al. (2005), Lemoine et al. (2006), and Konopliv et al. (2011), while those converging toward a smaller value of 0.12–0.13 are reported by Balmino et al. (2005) and Marty et al. (2009). A clear discrepancy exists between these two Love number values as their error bars do not overlap. The core radius is given by the color scale: the upper value of the Love number from Konopliv et al. (2011) suggests a core radius in the range of 1630–1830 km, while the lower value from Marty et al. (2009) suggests a smaller core radius.

(e.g., Rivoldini et al., 2011). This kind of endothermic phase transition from spinel to perovskite has been suggested as a requirement of mantle convective models for the early formation of Tharsis (Harder and Christensen, 1996; van Thienen et al., 2006). The size and state of the core, and the existence and size of a solid inner core, are also critical to understanding the cessation of an early martian dynamo (Acuna et al., 1999, Breuer and Spohn, 2006; Stevenson, 2001). Thus, the determination of the core size is a key objective for seismology, not just for the knowledge of present-day interior structure, but in order to constrain models for the geodynamical evolution of Mars.

The liquid or solid state of the core and mantle attenuation are also parameters that affect seismic-wave propagation and, thus, the design of future seismic experiments on Mars. A liquid (outer) core may result in a seismic shadow zone, as observed on the Earth, and a highly attenuating mantle, due to volatiles and, perhaps, locally warm temperatures, can strongly reduce the amplitudes of the SP body waves, as may be the case on the Moon (Nakamura, 2005). A liquid core is likely and is supported by the Phobos tidal acceleration value (Bills et al., 2005) and by the large k_2 value. As noted by Lognonné and Mosser (1993) and by Zharkov and Gudkova (1997), the low value of the martian Q at the Phobos tidal period implies an unrealistically low intrinsic Q for the planet if the core is solid. In contrast, a Q corresponding to silicate material is found for a model with a liquid core (Lognonné and Mosser, 1993). The extrapolation from the tidal Q to the seismic Q can be performed using either the low frequency dependence Anderson and Given (1982) observed on the Earth, or viscoelastic models (Nimmo and Faul, 2013; Nimmo et al., 2012). In the first case, a shear Q of about 300 at a period of 1 s is found (using a power law of 0.15; Lognonné and Mosser, 1993; Zharkov and Gudkova, 1997), as compared with a Q of 85 at the 5 h 32 min Phobos tide period. On the other hand, the second case yields a lower Q of about 130 at a period of 1 s (Nimmo and Faul, 2013). However, the viscoelastic theory, when used for the Moon, leads to theoretical Q that are up to a factor of two smaller than those seismically observed. Both methods however produce a seismic Q between value of the lower-mantle PREM (Dziewonski and Anderson, 1981) shear Q (about 310) and the upper-mantle shear Q (about 140). As the martian lithosphere is expected to be significantly thicker than Earth's, the intrinsic Q of martian surface waves with periods up to 200 s (which will have most of their energy in the upper 300 km) might be substantially greater than Earth's.

It is unknown whether significant scattering of surface waves will occur on Mars, however.

All other details of mantle structure remain largely unknown. In terms of seismological inferences, a key parameter will be the iron content of the mantle. Mocquet et al. (1996) have studied the effect of increasing iron content from 10% to 40%, and many other models include mantle iron contents ranging from 20% to 30% (Dreibus and Wänke, 1985; Gudkova and Zharkov, 2004; Sanloup et al., 1999; Zharkov and Gudkova, 2005). The main effect of an increase in iron content is to smooth the seismic discontinuities associated with α-olivine-to-β-spinel and β-spinel-to-γ-spinel transitions, as seen in **Figure 32** for both the density and acoustic velocity $v_k(v_k^2 = v_p^2 - 4/3v_s^2)$. For an iron content of 20%, the width of the transition zone at a radius between 2200 and 2400 km is seen to be between 50 and 100 km. Moreover, the discontinuity almost disappears for the high 40% iron content. These transitions contrast with those on Earth, for which both the reduced iron content and the higher pressure gradient result in sharp discontinuities, with a typical width of < 10 km (e.g., Tibi and Wiens, 2005). Reflections from mantle discontinuities on Mars might be less impulsive than reflections on Earth, and as a result, they might only be observable only at LPs, when the seismic wavelength is much greater than the width of the discontinuity, or below frequencies of 0.05–0.1 Hz. Consequently, these phases might be observed only for the largest quakes. In summary, we can expect that, as with the Moon, most of the mantle information will be obtained from direct P and S waves and from phases reflected at the core and the surface (PKP, PcP, ScS, and PP).

10.03.5.2 Martian Seismic Noise

The Viking seismic experiment failed to detect seismic activity largely because of the sensor's wind sensitivity. This wind noise was primarily a consequence of the seismometer's location. The seismometer was deployed on the lander platform and coupled with the ground via the elastic legs of the lander, leading the seismometer to detect lander vibrations due to noise. We can expect increased detection of seismic activity

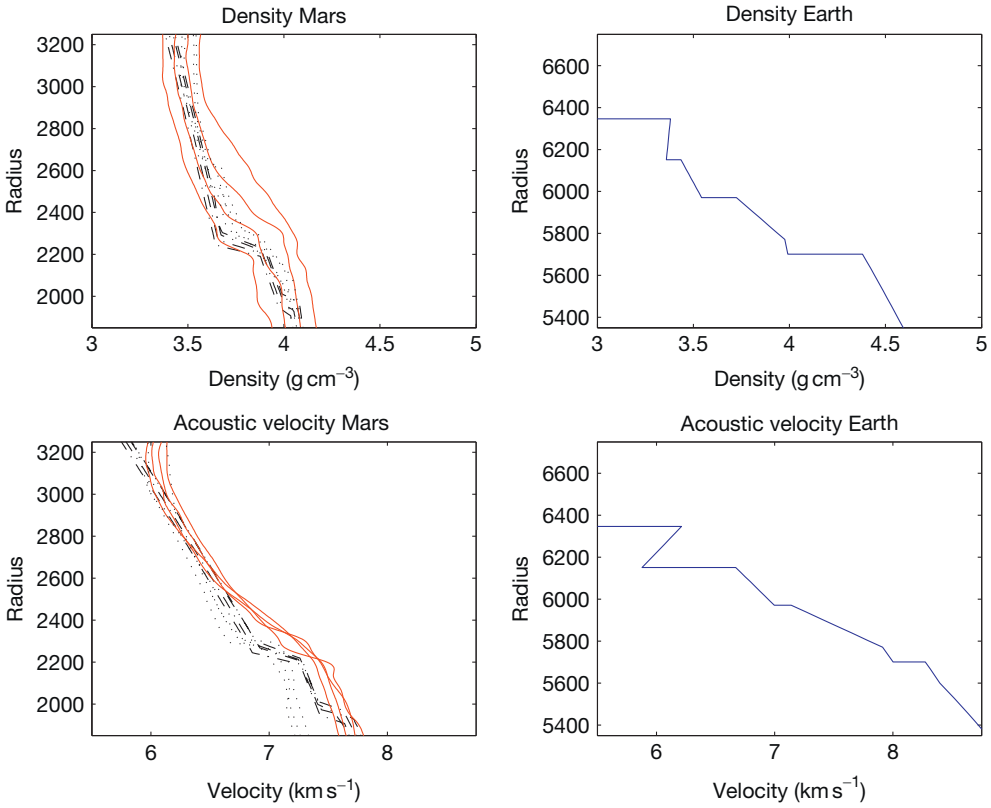

Figure 32 The top-left and bottom-left graphs show the density and acoustic-velocity models M1–M4 of Gudkova and Zharkov (2004), respectively, with Fe contents from 0.20 to 0.25 (0.20–0.22–0.24–0.25) (dashed black lines). In the left graphs, solid red lines represent the models of Mocquet et al. (1996) with Fe contents from 10% to 40% (0.1–0.2–0.3–0.4), and dotted black lines represent the models of Verhoeven et al. (2005) with Fe contents from 0.09 to 0.28 (0.09–0.2–0.25–0.28). An increase in Fe content will smooth the seismic discontinuity and widen the transition zone associated with the α-olivine-to-β-spinel and the β-spinel-to-γ-spinel phase conversions. For comparison, the two right graphs show these parameters for the PREM model (Dziewonski and Anderson, 1981). For the figure on the left for Mars models, the difference in discontinuity depths is mainly related to changes in the core-mantle boundary temperature. A temperature of approximately 2100 K is taken at the core-mantle boundary for the model of Gudkova and Zharkov (2004), whereas a more complex model, with temperature inversion in the mantle and a mantle temperature approximately 500 K colder at the depth of the discontinuities, is taken by Mocquet et al. (1996). These colder temperatures in this model shift the discontinuity to a shallower depth. The temperatures for the models of Verhoeven et al. (2005) are those reported by Breuer and Spohn (2003).

from a future mission, however, given that the seismometer will be directly installed on the ground. Covering the seismometer with a rather simple windshield can strongly reduce wind effects. Field tests have demonstrated the effect of windshielding on Earth at a noise level almost comparable to the low noise model at periods of a few 10s of seconds (Lognonné et al., 1996), and we can therefore expect noise levels as low as 10^{-9} ms^{-2} Hz$^{-1/2}$ in the bandwidth 1–0.05 Hz, which is dominated by microseismic peaks on Earth.

Mars does not have an ocean (the major source of terrestrial noise between 0.07 and 0.14 Hz) or human activity. So, most of that planet's remaining seismic noise will be associated with the interaction of the atmosphere with the subsurface. Lognonné et al. (1996) have shown that, even on Earth, prototype Martian seismometers can reach low noise levels at a quiet site, when protected by a windshield, leaving the overall ground deformation as the ultimate and unescapable noise on a planet with a windy atmosphere. This has been well-documented on Earth, at LPs (Sorrells, 1971; Sorrells et al., 1971) and at SPs of varying durations (Criswell et al., 1975; Steeples et al., 1997; Withers et al., 1996). Wind-generated microseismic noise on Mars has been estimated by Lognonné and Mosser (1993) and later modeled with Large Eddies Simulations by Lognonné et al. (2012), while temperature-generated noise was estimated by van Hoolst et al. (2003).

Ground accelerations produced by the direct deformation of the martian surface due to wind pressure fluctuation could have peak-to-peak amplitudes of a few 10^{-9} m s^{-2}, in the range of 1–0.1 Hz, for wind speeds of ~4 m s^{-1} on non consolidated, regolith-type subsurface (Lognonné and Mosser, 1993; Lognonné et al., 2012). Strictly speaking, these fluctuations are not noise, but the ground deformation generated from the pressure field, and they can therefore be partially corrected by recording the pressure data (e.g., Beauduin et al., 1996).

Temperature variations are the other major source of noise for surface-installed VBB seismometers. However, as shown by van Hoolst et al. (2003), most of the temperature variations on Mars are associated with the daily cycle and can be approximated by a Fourier series with the fundamental mode (of 24 h 56 min) and its harmonics. Moreover, the thermal insulation of space-qualified seismometers can reach time constants larger than 2 h, and an additional wind/thermal shield can create additional attenuation. These two forms of protection reduce the temperature variations experienced by the sensor to $<10^{\circ}$ under martian conditions (Mimoun et al., 2012; Robert et al., 2012), leading to temperature fluctuations of a few tens of milli-Kelvins in the seismic band. An installation with a noise level comparable to terrestrial low noise model (e.g., about 10^{-9} m s^{-2} Hz$^{-1/2}$ in the seismic bandwidth, see Pedersen (1993)) is therefore the realistic goal of InSight.

10.03.5.3 Body-Wave Detection

Due to the lower event magnitudes, as compared with event magnitudes on Earth (see **Figure 13** in **Section 10.03.3**), the best signal-to-noise data from Mars will probably be found in the bandwidth of body waves and regional surface waves. Attenuation and the scattering of seismic energy are the main limitations on body-wave detection, and the importance of attenuation on Mars was originally pointed out by Goins and Lazarewicz (1979), who showed that, when operating with a free frequency of 4 Hz, the Viking seismometer was unable to detect remote events due to attenuation. For a Q of 325, which is obtained as explained in **Section 10.03.5.1**, and a velocity of 5 km s^{-1}, S-wave amplitudes are reduced by a factor of 10 after 1200 km of propagation at 1 Hz. Amplitudes at 4 Hz are reduced by the same amount after only 300 km of propagation. The amplitudes of body waves are plotted in more detail in **Figure 33(a)** and **33(b)**, including those of ScSH. The amplitudes are computed for one frequency band (0.3–1.5 Hz) for an isotropic surface shallow source (quake) of seismic moment of 10^{14} and 10^{15} Nm. Transmission across a crust–mantle boundary is taken into account, as are geometrical spreading and attenuation. Sohl and Spohn (1997) model A is used, with both crust and mantle discontinuities, thereby affecting the amplitude for epicentral distance $<20^{\circ}$. While depending on the seismic model used, these amplitudes mainly depend on the attenuation used. Here, the model uses a mantle shear Q provided by $Q_{\mu}=325\times T^{-0.15}$, where T is the period in seconds.

Figure 33(a) shows body-wave amplitudes as a function of frequency at a distance of 30°. Amplitude is relatively independent of epicentral distance only for P waves in the frequency band 0.1–1 Hz. Consequently, this frequency band, with a 1-ng resolution, was chosen for the Optimism seismometer (Lognonné et al., 1998a). At higher frequencies (0.5–2.5 Hz bandwidth), however, amplitudes decrease rapidly with source–receiver distance and are less than S-wave amplitudes at the longest periods. For an instrument with noise characteristics of 10^{-8} ms^{-2} Hz$^{-1/2}$, noise levels of ~2.5 ms^{-2} RMS will be expected in the 0.5–2.5 Hz frequency bandwidth, limiting the detection of S waves at large epicentral distances to quakes with moments larger than 10^{15} Nm.

SP body waves are also sensitive to scattering. This relationship has been demonstrated on the Moon and results from intense crustal fracturing due to meteoritic impacts, as well as tectonic structure (e.g., Dainty and Toksöz, 1977; Nakamura, 1977b). On the Earth, scattering is also very strong in volcanic regions. These combined effects suggest that significant scattering may occur in volcanic areas on Mars, particularly in the Tharsis region. For body waves, scattering reduces the peak-to-peak amplitudes by producing conversions (mainly P to SV, P to SH), while spreading this energy in time. This leads to energy transfer from P to S waves up to an equipartition given by $E_p=(v_s^3/v_p^3)(E_s/2)$, where E_p and E_s are the energy of P and S waves, respectively, and v_p and v_s are the velocities of P and S waves (e.g., Aki, 1992; Papanicolaou et al., 1996).

Conversion of P-to-S energy during scattering dominates S-to-P conversion (Aki, 1992). As such, near-surface scattering can greatly reduce the amplitude of P waves both near the source (assuming shallow events) and near the receiver. This amplitude reduction can occur initially as the energy propagates outward from the source into the mantle, and again during the upward propagation from the mantle to the surface, near the receiver. As a result of the shrinking amplitude, the P-wave energy can be reduced by a factor of ten, with larger amplitude reduction due to the length of the coda.

The potential efficiency of a future network configuration can be investigated using these results, as shown by Mocquet

Figure 33 (Continued)

(1999). Figure 34(a) details such a study for a possible network configuration, assuming total detection for signals with accelerations $>10^{-8}$ m s^{-2} peak-to-peak. They show that a rate of 60% can be achieved for the detection of quakes with seismic moment $>10^{14}$ Nm, which corresponds to Earth moment magnitudes >3.2. As shown in Figure 13, depending on the seismic activity, between 40 and 400 quakes with at least this seismic moment are expected to occur during one martian year. Note that the four-station network configuration, in contrary to the lunar seismic network, will allow a much better characterization of the core, with antipodal stations near Hellas Planitia. Figure 34(b) shows the increase in coverage for a network configuration with an additional station, which would also provide redundancy. Source localization errors will affect the determination of the seismic velocities and might be large for a network with only a few stations. The impact of the number of station used in the location and the source location error has been discussed by Gagnepain-Beyneix et al. (2006), for the lunar case.

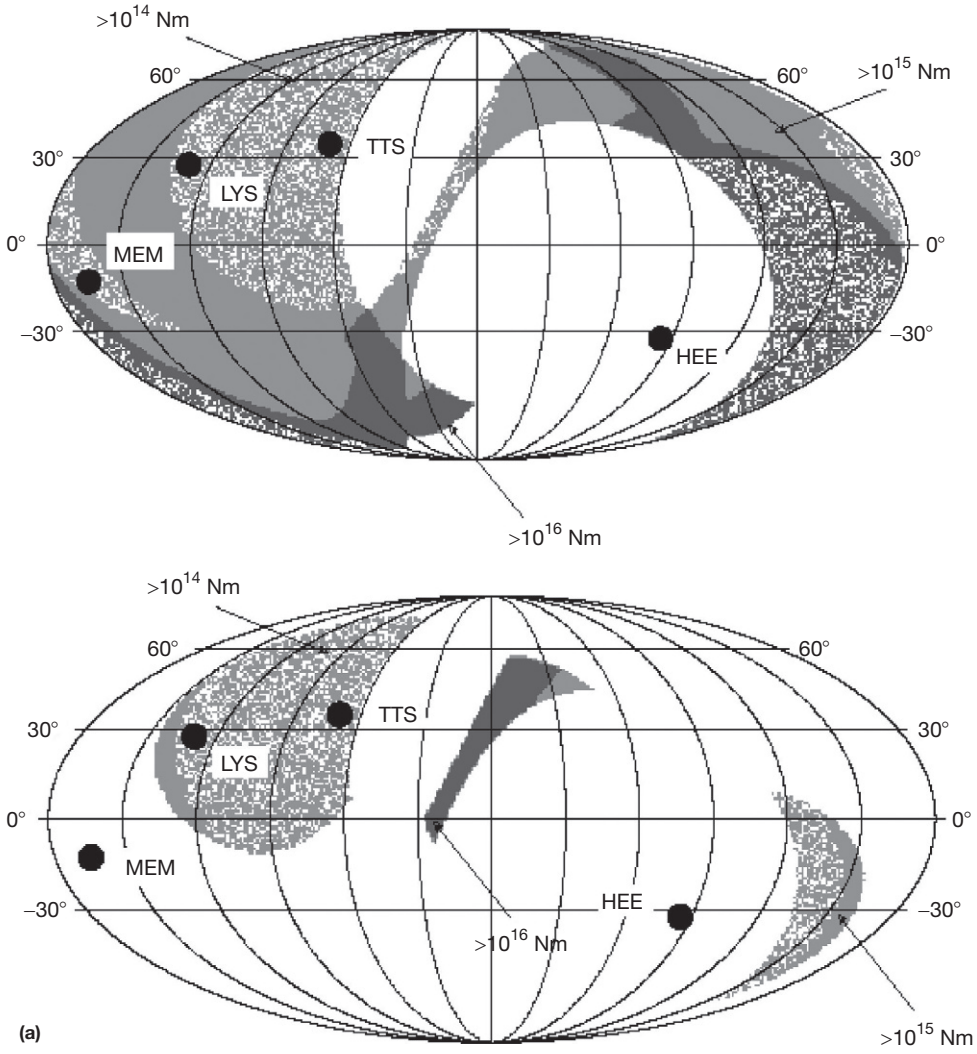

Figure 34 (Continued)

Figure 33 (a) Detection performance of the InSight VBBs and SPs (red line, requirements, black dashed line, capabilities) with respect to the typical amplitude spectral density of ground acceleration generated by marsquakes of 1014-1015 Nm, at 30° of epicentral distance for the model of Sohl and Spohn (1997). Shallow earthquakes might have amplitudes larger by a factor of 2, due to surface amplification. The amplitude power spectrum of P and S body-wave packets have been computed with a duration of 15 s. The amplitudes of normal modes for a 1018 quake are also provided. (b) Peak-to-peak amplitude in the 0.3–1.5 Hz frequency bandwidth with respect to epicentral distance for 10^{14}-Nm (continuous line) and 10^{15}-Nm (long dashed line) seismic moment quakes at the surface. Blue = P, red = S, black = ScSH, and green = PKP. The light blue lines represent the InSight requirement RMS noise and the system's capability in this frequency bandwidth. Large amplitude variations between 60° and 90° are related to the mantle discontinuities of the Sohl and Spohn (1997) model.

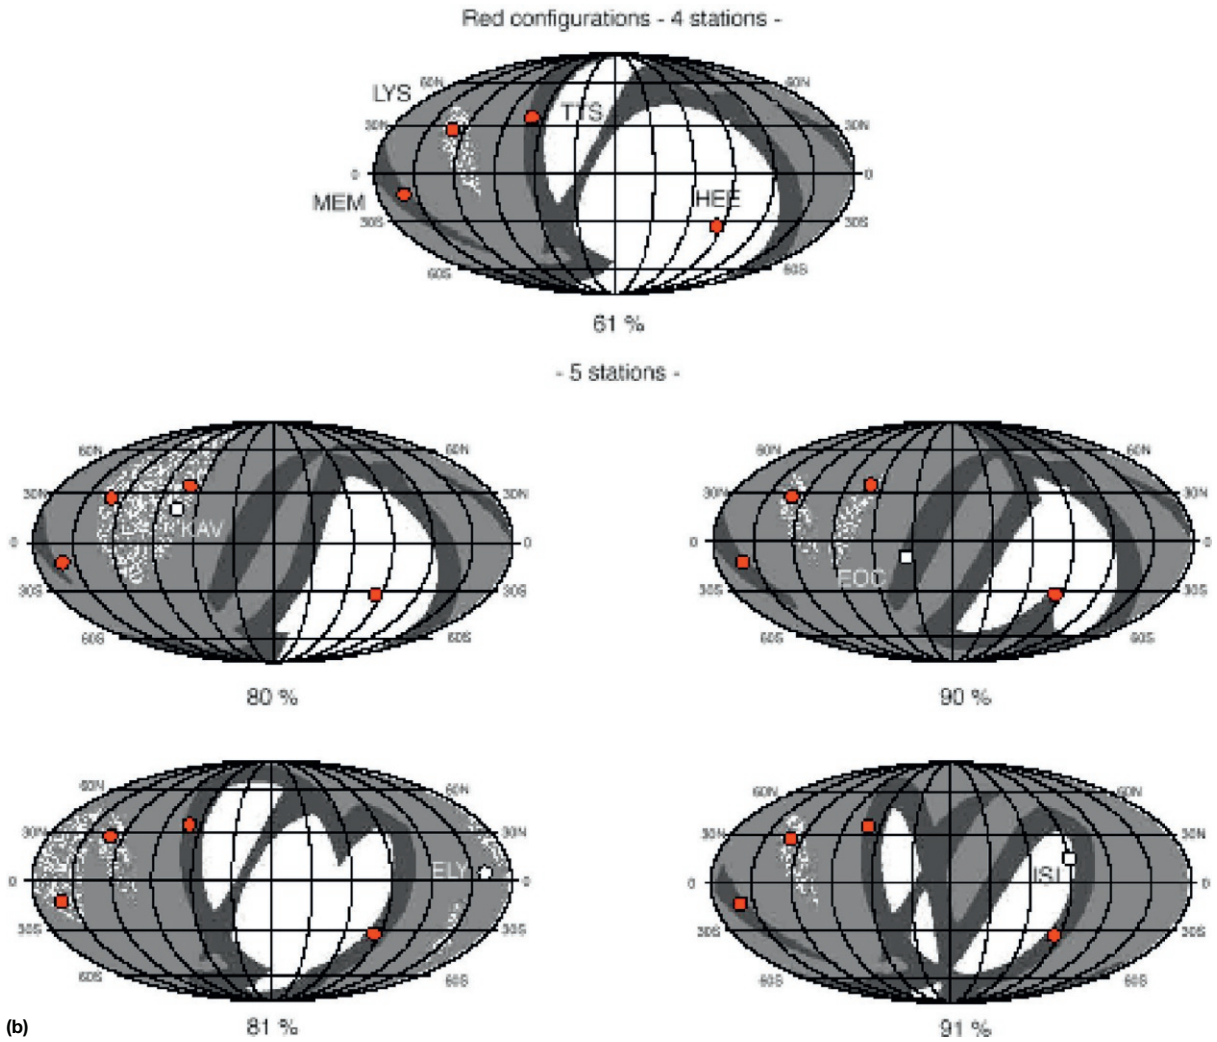

Figure 34 (a) Top: Detection zone of P and S waves for one of the studied configurations in the former Netlander project (MEM, Menomnia Fosae; LYS, Lycus Sulci; TTS, Tempe Terra South; HEE, Hellas East). The white zone to the east of TTS corresponds to the joint shadow zone of MEM and HEE. Note that the detection efficiency is very high in the Tharsis area, where small quakes of seismic moment of 10^{14} Nm might be detected. Bottom: Detection zone of a PKP wave in at least one station and of P and S waves in the three other stations. The success rate is 16%, leading to about 22 quakes detected during the 2 years of operation. Reprinted from Lognonné P, Giardini D, Banerdt B, et al. (2000) The NetLander very broad band seismometer. *Planetary and Space Science* 48: 1289–1302, with permission of Planetary and Space Science. (b) Zone covered by a successful detection of P and S waves on at least three stations for a network with four or five stations. The top figure recalls the detection zones with only four stations, while the other figures represent networks with five stations. In this case, the red dots represent the four nominal landing sites of the Netlander mission. The white dot is a possible new landing site. The shaded zone corresponds (from gray to black) to the detection thresholds from magnitude 3.5–5. Note the large increase of the total surface covered by the network presented below each figure. Note also that the dashed gray zone, corresponding to the detection of small quakes of seismic moment 10^{14} Nm, either has a larger surface or appears in several different spots, each of which is associated with a successive detection on the three closer stations.

10.03.5.4 Normal Mode Excitation and Tidal Observations

With direct body-wave travel-time analysis, the extraction of internal structure information requires precise event localization and, hence, several quakes recorded by at least three stations. For each quake, four data points can then be related to the four source parameters, while the two other points constrain the interior model. Surface-wave and normal-mode analyses have the potential to provide useful information on the interior with fewer stations. As noted above, a cumulative activity of 10^{18}–10^{19} Nm year^{-1} indicates that quakes with moments as large as 10^{18} Nm could be recorded if the station is operated for one martian year or more. The excitation of normal modes by marsquakes was studied by Lognonné et al. (1996) and later by Gudkova and Zharkov (2004). Both studies concluded that normal modes between 5 and 20 mHz with a noise level of 10^{-9} ms^{-2} Hz$^{-1/2}$ could be observed using stacked quake records with a cumulative 10^{18}-Nm moment or from single-record analysis of the greatest quakes (**Figure 35(a)**). Normal modes will peak, with a signal-to-noise ratio of about 10, within Q-cycle windows for such quakes, which correspond to moment magnitudes of 5.5 (Lognonné et al., 1996). Given

Figure 35 Acceleration amplitude spectrum for a quake with strike, deep, and rake angles of 45° and a seismic moment of 10^{18} Nm. The azimuth is 20°, and the epicentral distance is 90°. The depth of the event is 30 km. The spectra for Mars are shown in (a). Those for the Earth are in (b). At 5 mHz, the amplitudes exceed 1 ng Hz$^{-1/2}$ and are a factor 4 greater than those observed on the Earth. Note that, below 10 mHz, the fundamental modes constitute most of the signal.

the size of the planet, however, the mode frequencies for a given angular order are typically twice the mode frequencies on Earth (Figure 35(b)). The observation of normal modes below 5 mHz, which are the most sensitive to core size, will be more challenging with such quakes, and modes such as ${}_0S_2$ might remain below the instrument or station noise, especially because of temperature fluctuations due to the operation of the first Mars seismometers at the surface.

As noted by Lognonné and Mosser (1993) and van Hoolst et al. (2003), an alternative core structure constraint will be a surface-sensor measurement of the solid tide amplitude, and, in turn, the associated Love numbers. A successful measurement will be mainly determined by the temperature noise and will require a stack of year-long time series. van Hoolst et al. (2003) have predicted a noise level of about 0.5 K RMS in a frequency bandwidth of 1 mHz around the Phobos tide, based on the Viking temperature data. Both temperature decorrelation and thermal protection can reduce this signal by a factor of 100–250 after data processing, leading to a final noise level of 2.5–1 ngal after one martian year of stacking and a core-determination error equal to 60 km for 1 ngal of noise (Figure 36).

10.03.5.5 Surface Waves

Though the Apollo seismometers recorded no surface waves on the moon, the seismometers bound for Mars are expected to have better LP performance, and the predicted larger magnitude of marsquakes suggests the possibility of surface-wave detections on Mars in the future. By sampling the crust, lithosphere, and upper mantle, surface waves will be an important source of information. Their group velocities, for example, are very sensitive to the crustal thickness, with 10% typical variations for crustal variations of 20 km (Figure 37). The sensitivity of surface waves to the upper mantle will also be important, and the group velocity of surface waves (or the differential group velocity between the fundamental and the overtones) varies by 5–10% for the models of Mocquet et al. (1996) with different iron contents (Figure 32).

Quake localization errors and the effects of lateral variations on the surface waves will likely lead to difficulties in data analysis, however, and these errors will have the greatest impact if only a limited number of stations are deployed, possibly producing errors in the determination of spherically symmetric models of the mantle.

In the case of a single-station approach, as was designed for the InSight project, determining the epicentral distance based on surface waves will be possible after the first detection of the R1, R2, and R3 surface-wave packets generated by a larger quake. The differential travel time between R3 and R1 packets will indeed provide a measure of the averaged propagation velocity of surface waves over the length of the planet's great circle. Once this surface-wave velocity is known, the epicentral distance can be determined as soon as both the R1 and R2 surface-wave packets are defined (Lognonné et al., 2012). This determination will then

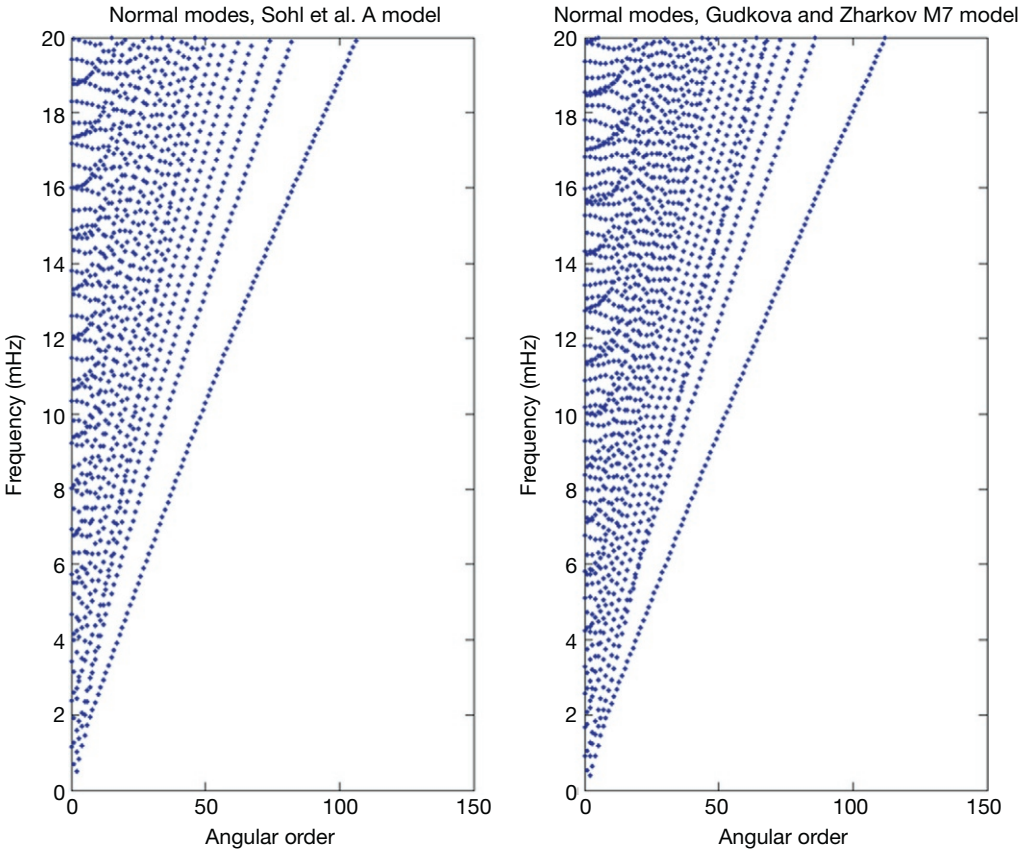

Figure 36 Normal modes for two Mars models: Model A from Sohl and Spohn (1997) and model M7 from Gudkova and Zharkov (2004). Differences in the mode frequencies are about 5–10%.

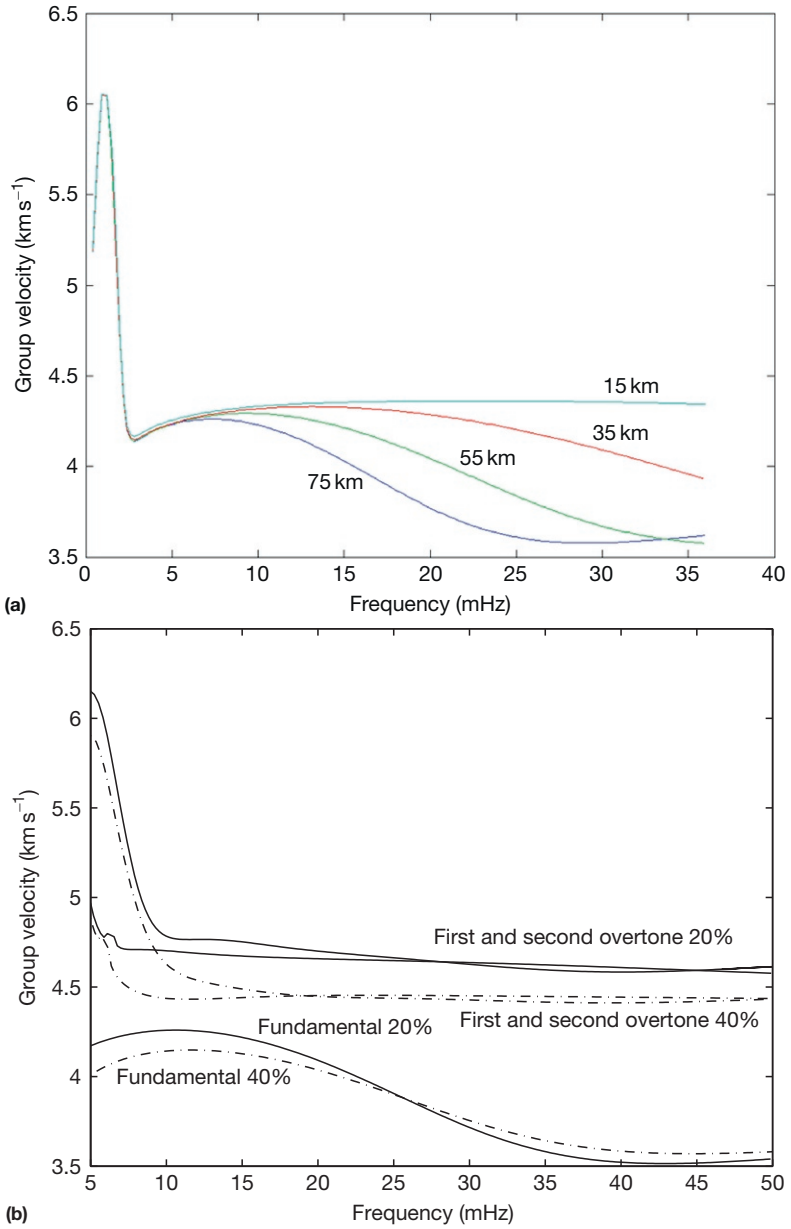

Figure 37 (a) Sensitivity of the Rayleigh waves to the crustal thickness. Model B of Sohl and Spohn (1997) is used, and the crustal velocity and density, which are assumed to be homogeneous, are those of this model. Variations of 10% in the group velocity are found for about 20 km of crustal thickness variation for frequencies in the range of 10–30 mHz. (b) Group velocities for two models of Mocquet et al. (1996) and for the fundamental mode and first and second overtones. The iron content of the mantle is indicated as a percentage. Note that we have added a crust of 50-km thickness to these models, using the Sohl and Spohn (1997) crustal structure. Group velocities without this crust can be found in Lognonné (2005).

enable the creation of interior models through the joint inversion of the R1, R2, P, and S arrival times (Panning et al., 2012).

If two stations are available, the location of quakes via surface waves can be done by measuring the back-azimuth of the surface waves. **Figure 38** shows that, for typical landing sites around the Tharsis bulge, errors in the relative epicentral distance of $<2.5\%$ can be achieved over a wide equatorial band of the planet ($\pm 20^{\circ}$ latitude), when back-azimuth errors of 15° are assumed. Such measurements could resolve the major differences among currently proposed mantle models (**Figure 32**). However, limitations result from the sensitivity of surface-wave azimuth to lateral variation in crustal thickness, and these limitations will prevent the detection of smaller differences, such as those related to the FeO content in the mantle (Mocquet et al., 1996). On Earth, such azimuthal variations typically reach 10°, and it is possible that lateral variations in crustal structure on Mars will lead to larger effects (Larmat et al., 2008). However, as observed on Earth, much of the lateral variations of surface waves can be modeled with a priori constraints on the lithosphere and upper mantle (Nataf and Ricard, 1996). With the recently improved estimates in crustal thickness (Zuber, 2001), lithospheric thickness

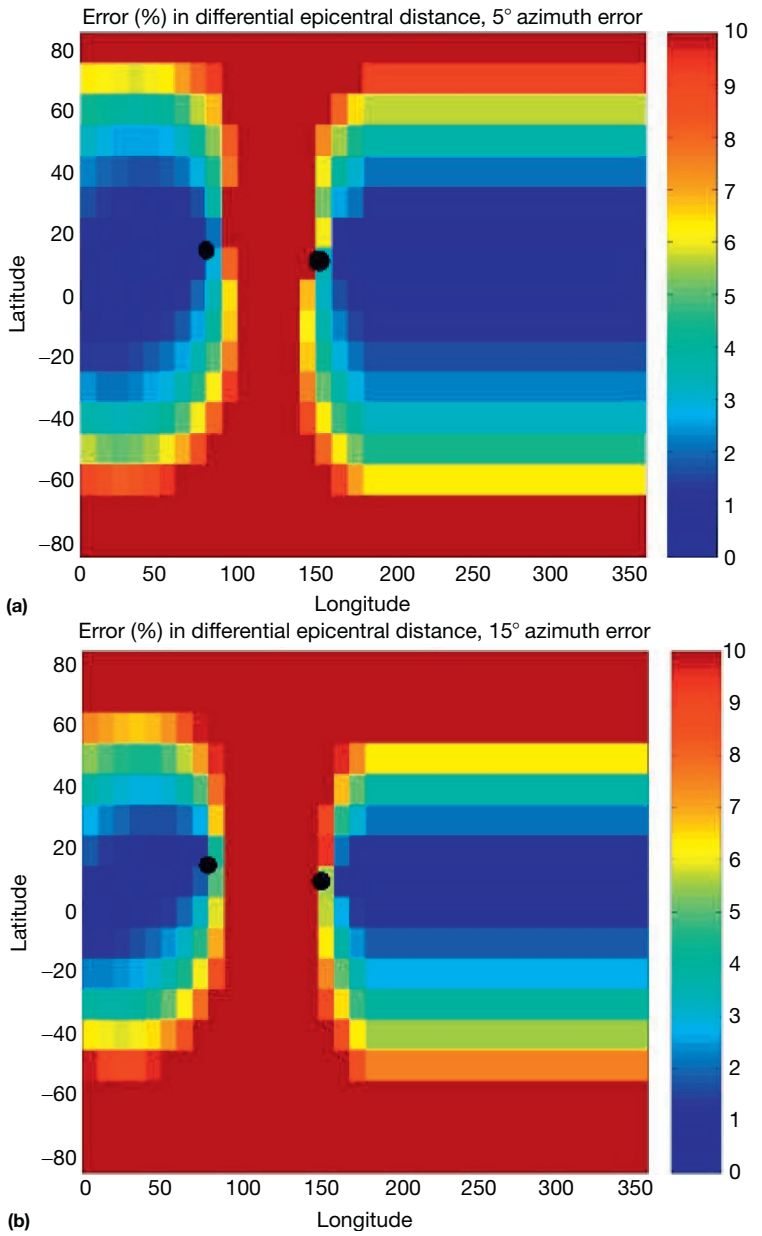

Figure 38 Relative error in the determination of the differential epicentral distance for surface-wave analysis based on the back-azimuth determination in two cases. The differential epicentral distance is the difference between the two epicentral distances (i.e., distance between the epicenter and each station). (a) is for a 5° error, and (b) is for a 15° error. The location of the two stations (filled black circles) is 11° N, 152° W and 15° N, 80° W, and these locations correspond to two landing sites proposed for the NetLander Network, a canceled project. Only locations with an error smaller than 10% are shown, with the latter limit being the a priori difference between the seismic values proposed by the models shown in **Figure 32**.

(Belleguic et al., 2005) and crustal heating, we can expect future developments in modeling the effects of crustal and lithospheric lateral variations on surface waves and associated corrections.

10.03.6 Concluding Remarks

Planetary seismology began almost concurrently with planetary exploration, with seismometers onboard the Ranger probes in the early 1960s. As shown by the Apollo seismic network, a body might be much less seismically active than Earth, but it can still produce several recordable events per day, due to very low noise levels. Both meteorite impacts and moonquakes were recorded on the Moon over a period of more than 7 years. Deep moonquakes remain enigmatic, with repeated brittle failure inferred at specific source locations on the basis of waveform similarity and tidal periodicities. Major questions remain, however. Tidally generated stresses are small relative to those expected to result in failure, and the reasons for brittle failure at depths of 800–1000 km are

not well understood. Large uncertainties regarding the locations of many source regions also exist, and to date, it has not been possible to determine focal mechanisms for these events, although the prominence of shear-wave arrivals in the seismograms suggests that shear failure is occurring.

Meteorites and moonquakes, together with known artificial impacts, have allowed first-order investigations of depth-related variations in seismic velocity. Crustal thickness estimates made shortly after the Apollo missions were suggested to be on the order of 60 km, but more recent studies have revised these estimates to 30–45 km. Seismic-velocity estimates to depths of ~1000 km are possible, but source receiver geometries prohibit direct seismic investigation of lowermost mantle and core structure. Differences among current model estimates for mantle seismic velocities reflect a combination of network geometry, instrument limitations, and likely 3D structure. Thus the seismic exploration of the Moon is far from complete. Large uncertainties remain in the internal structure, and major discontinuities, such as the core–mantle, lower–upper mantle, and mantle–crust transitions, are still not well constrained. Moreover, currently unmapped geographical variations in crustal and mantle structure are a critical key to understanding early lunar evolution.

The work reviewed in this chapter demonstrates that the technology exists to perform ground-based seismic experiments on the Moon and on Mars, and that exciting possibilities also exist for remote detection of seismicity and seismic waves, via atmospheric sounding by satellites. This method could prove fruitful in future studies of Venus, for which long-lived ground-based observations are severely challenging due to surface conditions. In addition, remote detection could allow investigations of the giant planets.

Forty years after Viking, the InSight Discovery mission is expected to reopen the field of planetary seismology by installing a single sensor station on Mars in the fall of 2016. We hope that this station will soon be followed by others, not only on Mars, but on other terrestrial bodies in the solar system. This step is crucial for determining the internal structure of the telluric planets, and it can lead to a better understanding of these bodies and, through comparison, a better understanding of Earth.

Acknowledgments

Catherine Johnson acknowledges the support provided by the Natural Sciences and Engineering Research Council of Canada. Philippe Lognonné acknowledges the support provided by CNES, PNP, and INSU/CNRS, which have been involved with his research for the last 10 years. The authors also thank B. Romanowicz, A. Mocquet, Y. Nakamura, and M. Knapmeyer for their constructive reviews of the original and revised chapters. In addition, the authors thank several colleagues who contributed to this chapter through discussions, figures, and ideas, including B. Banerdt, A. Mocquet, R. Garcia, D.Mimoun, H. Chenet, J. Gagnepain-Beyneix, T. Spohn, M. Knapmeyer, D. Giardini, R. Weber, M. Wieczorek, M. Jellinek, and J.-F. Blanchette-Guertin. A special thanks to all the engineers, technicians, and staff members who have worked to create the instruments used in the various projects described in this paper. This is an IPGP contribution 3608.

10.04.1 Introduction

The rotation of the terrestrial planets of our solar system is remarkably diverse (see Table 1). The Earth and Mars spin much faster than their orbital motion, whereas the rotation periods of Venus and Mercury are commensurate with their orbital periods. The two innermost planets have very small obliquities (the angle between the orbital plane and the equator of the planet) as opposed to the large obliquities of about 25° for the Earth and Mars. Mercury, the Earth, and Mars have a prograde rotation, that is, their rotational motion is in the same sense as their orbital motion; Venus, however, has a retrograde rotation. Mercury is the only solar system planet in a spin–orbit resonance: its rotation period is two-thirds of its orbital period.

Mass M, mean radius R, semimajor axis a, eccentricity e, obliquity ε, siderial rotation period P_{rot}, orbital period P_{orb}, gravitational coefficients J_2 and C_{22}, normalized moment of inertia, and precession rate for the four terrestrial planets. Orbital elements are for J2000. See **Sections 10.04.3, 10.04.4**, and **10.04.5** for more information and references. Gravitational coefficients are from Smith et al. (2012) for Mercury, Konopliv et al. (1999) for Venus, and Konopliv et al. (2011) for Mars. A star indicates that the value has not been observed but has been calculated theoretically.

Planets accumulate rotational angular momentum from the relative motion of planetesimals at collision. The angular momentum acquired in an individual impact can be large and in any direction. However, there is a high degree of cancellation for the small planetesimals and the net rotation depends on a systematic bias in the distribution of the obtained angular momentum. For a realistic distribution of planetesimal eccentricities, planets accreting from a uniform surface density disk of small planetesimals rotate progradely although much slower than the Earth and Mars (Dones and Tremaine, 1993; Lissauer and Kary, 1991; Lissauer et al., 1997; Ohtsuki and Ida, 1998). A planet can acquire faster rotation in a nonuniform disk (see, e.g., Lissauer et al., 2000). On the other hand, during the late stages of terrestrial planet accumulation, one or a few large impacts can cause a planet to rotate very rapidly at nearly the breakup rate, so that the rotation of the planet is expected to be dominated by those random impacts. Large impacts can also determine the initial obliquity of a terrestrial planet. Due to the dominance of random phenomena and insufficient understanding of planetary accretion, definitive predictions regarding the accumulation of rotational angular momentum for each individual terrestrial planet cannot be made. Nevertheless, if giant impacts are solely responsible for the final spin state after planet formation, both the spin rates and obliquities should be isotropically distributed and prograde and retrograde spins are equally possible (Agnor et al., 1999; Chambers, 2001; Kokubo and Ida, 2007). Schlichting and Sari (2007) suggested that a final preference for prograde rotation results from the systematic prograde rotation of each protoplanet and from the accretion of remaining planetesimals in the post-giant impact phase.

In this chapter, we focus on the variations in the rotation of the terrestrial planets on short timescale and review how the rotation could have evolved from their primordial rotation state. We emphasize the broad geophysical and planetological significance of rotation studies and show that they provide a direct and unique tool to explore otherwise difficult to obtain global properties of the terrestrial planets. Rotation studies used to belong to the realm of celestial mechanics and the planets were usually considered to show a rigid rotational behavior. However, the internal structure and dynamics of a planet can have a large impact on its rotation. Also, the atmosphere, through exchanges of angular momentum with the solid planet, can cause the rotation of a planet to change. Here, we review rotation studies from a geophysical point of view with only limited information on the celestial mechanics. Tidal friction is a classical example of a geophysical effect on planetary rotation and the main cause of the secular braking of the rotation of the Earth. Dissipation of tidal energy in a planet delays the time of high tide, and the gravitational torque from the Sun on the tidal bulge – the tidal torque – changes the obliquity and tends to drive the planet to an equilibrium rotation rate, which is synchronous with its orbital motion for a circular orbit. Other dissipative effects, such as dissipative core–mantle interactions and thermal tides of the atmosphere, can also contribute substantially to the spin evolution of the planets. Also fluid layers, such as an atmosphere and a liquid core, can significantly change the rotation of the mantle and the crust on short timescales because they can rotate differentially with respect to the mantle and crust and interact with the solid layers. As an example, short periodic rotation variations as nutation and libration depend sensitively on the state of the core of the planet and can inform on core properties. The determination of the present core state by rotational means has profound implications for our understanding of the thermal evolution and the magnetic field history of the planet, as well as for the composition and thermal state at the time of formation.

Accurate present mean rotation states have been derived from Earth-based radar observations and space missions visiting the terrestrial planets. Periodic rotation variations are more difficult to measure, and only the largest components have been obtained with limited precision. More accurate data on all aspects of rotation variations and a full exploitation of the potential of rotation studies are foreseen with improved ground-based radar observations, upcoming orbiting spacecraft missions (such as the ESA BepiColombo mission to Mercury), and plans for radio science experiments with landers on the surface of terrestrial planets (such as with the NASA InSight mission to Mars).

The outline of this chapter is as follows. In **Section 10.04.2**, we introduce the basic concepts and equations, which are applied to Mars, Venus, and Mercury in **Sections 10.04.3,**

10.04.4, and 10.04.5, respectively. We start Section 10.04.2 with the equation of conservation of angular momentum and discuss properties of precession, nutation, polar motion, and rotation rate variations. We review in some detail the Liouville equation approach for the study of rotation variations and also briefly describe the Hamiltonian method for the case of rotation variations on long timescales. In the last part of Section 10.04.2, an overview is given of the secular effects of dissipative processes on the rotation of terrestrial planets. After an introduction on the current rotation state of Mars and its long-term variations, we present in Section 10.04.3 an overview of the nutation, length-of-day (LOD) variations, and polar motion of Mars in relation with its interior structure and atmosphere. The evolution of the rotation of Venus to its present state is reviewed in Section 10.04.4, together with its periodic rotation variations. In Section 10.04.5, we present an overview of the evolution and capture into resonance of Mercury and review its librations. In particular, we explain that accurate measurements of the librations and of the obliquity of Mercury put strong constraints on its interior structure.

10.04.2 Theoretical Foundations

10.04.2.1 Conservation of Angular Momentum

10.04.2.1.1 Precession

Rotation variations of the terrestrial planets are usually studied in a Newtonian approach. General relativistic effects are small because the squared velocities of the planetary motions are much smaller than the squared speed of light. Moreover, the ratio of the Schwarzschild radius to the radius of the planets is extremely small (for the Earth, about 1.4×10^{-9}). For the rotation variations of the Earth, the general relativistic effects have been shown to be negligibly small, except for an additional contribution to precession (e.g., Bizouard, 1995). This so-called geodetic precession, though larger than the observational accuracy, can nevertheless not be separated from Newtonian precession because of uncertainties in the flattening of the Earth. Since the general relativistic effects on rotation variations are expected to be equally small for the other terrestrial planets and the observational accuracies are a few orders of magnitude larger than for the Earth, we neglect the general relativistic effects here. In this approximation, we describe the rotation variations with respect to 'inertial reference frames' with origin in the mass center of the planets.

The fundamental equation governing the rotation of a terrestrial planet is the conservation equation for angular momentum valid in an inertial reference frame:

$$\frac{\mathrm{d}\vec{H}}{\mathrm{d}t}=\vec{L} \qquad [1]$$

Here, t is time, $\vec{H}$ is the spin angular momentum of the planet, and $\vec{L}$ is the external torque acting on it. If no external torque is applied on the planet, eqn [1] shows that the angular momentum will not change in space. However, other solar system bodies exert a gravitational torque on the nonspherically symmetrical terrestrial planets. This torque can be derived from the gravitational potential $V\left(\vec{r}\right)$ of the planet at the position $\vec{r}\,(r,\theta,\lambda)$ of the mass center of a perturbing solar system body, which can generally be expressed as

$$V\left(\vec{r}\right)=-\frac{GM}{r}\sum_{l}\sum_{m=0}^{l}\left(\frac{R_\mathrm{e}}{r}\right)^{l}[C_{lm}\cos(m\lambda) + S_{lm}\sin(m\lambda)]P_{lm}(\cos\theta) \qquad [2]$$

where M is the mass of the planet, R_e the mean equatorial radius of planet, θ the colatitude (90° declination), and λ the longitude (hour angle) of the perturbing body. The origin of the inertial reference frame is chosen in the mass center of the planet. The universal gravitational constant is denoted by G, and l and m are the degree and the azimuthal order of the associated Legendre function P_{lm}. Degree-one terms are zero because the origin of the coordinate system is chosen to be at the center of mass of the planet (Heiskanen and Moritz, 1967). The torque $\vec{L}$ exerted by a solar system body with mass M^* at position $\vec{r}$ on the planet can then be expressed as

$$\vec{L}=M^*\,\vec{r}\times\vec{\nabla}\,V \qquad [3]$$

As the magnitude of the terms in eqn [1] decreases rapidly with increasing degree l for bodies far from the planet ($r\gg Re$), only the second-degree terms are included, even in the most advanced and accurate rotation studies, except for the Earth–Moon system. In this approximation, the planet is thus considered to be a triaxial ellipsoid and the torques are proportional to the mass of the perturbing body and inversely proportional to r^3, where r is distance between the centers of mass of the two bodies. The torque is then often approximately written as

$$\vec{L}=3\frac{GMM^*}{r^3}(\hat{r}\times\mathbf{I}\cdot\hat{r}) \qquad [4]$$

(e.g., Bills, 2005a). Because the torque rapidly decreases with increasing distance from the planet, only the torques of the massive Sun and the natural satellites orbiting the planet must be considered.

When the planet is not in a spin–orbit resonance, the external solar torque averaged over the orbital period has only a component in the orbital plane perpendicular to the rotation vector (e.g., Chapter 3.10; Stacey, 1992). Therefore, both the norm of the angular momentum and its component in the direction perpendicular to the orbital plane are constant in time. As for a spinning top, the constant (time-independent) part of the gravitational torque then causes the angular momentum axis to precess about the normal to the orbit of the planet at constant obliquity. For a planet that is not in a spin–orbit resonance, the precession rate can be approximated by

$$\dot{\psi}=\alpha_\mathrm{P}\cos\varepsilon=-\frac{3}{2}\frac{n^2}{\Omega(1-e^2)^{3/2}}J_2\frac{MR^2}{C}\cos\varepsilon \qquad [5]$$

(see, e.g., Smart, 1953), where α_P is the precession constant, Ω the mean rotation rate of the planet, M the total mass, R the mean radius, n the mean (orbital) motion, e the eccentricity, and $J_2\equiv-C_{20}=(C-\overline{A})/MR^2$ the degree-two zonal gravity coefficient. The principal moments of inertia of the planet are denoted by $A<B<C$, and $\overline{A}=(A+B)/2$ is the mean equatorial moment of inertia. Obliquity ε is the angle between the equator and the orbital plane, and longitude ψ is an orientation angle of the angular momentum axis measured from the center of the circular path of precession (we assume here that the orbit

is fixed). A dotted quantity, such as $\dot{\psi}$, indicates the time derivative of that quantity. Interesting to note is that the precession rate (eqn [5]) only depends on the degree-two, order-zero coefficient of the gravitational potential of the planet.

For rapidly rotating planets (such as the Earth and Mars), the polar flattening is essentially due to rotation and proportional to Ω^2 (e.g., Jeffreys, 1952), and eqn [5] shows that the precession rate is proportional to the rotation rate. For planets rotating so slowly that the rotational flattening is only a minor contribution to their flattening (as is the case for Mercury and Venus), the torque is essentially independent of the rotation rate, while the spin angular momentum of the planet is linearly proportional to it. Therefore, the torque causes relatively larger changes in the angular momentum when the rotation rate decreases, such as for a spinning top, and the precession rate is inversely proportional to the rotation rate for slowly rotating planets.

The principal geophysical interest of precession is that it allows determining the polar principal moment of inertia C of the planet. Measurements of the gravitational field of the planet yield very accurate values for differences between principal moments of inertia, such as J_2, but are not sufficient to determine the individual principal moments of inertia (see Chapter 10.05). The mean moment of inertia of a planet gives insight into the mass concentration toward the center and is a major constraint for models of the interior structure of the terrestrial planets (Chapter 10.02).

10.04.2.1.2 Nutation, polar motion, and length-of-day variations

Because terrestrial planets move on elliptical orbits and have a nonzero obliquity and a nonspherically symmetrical form, the external gravitational torque from the Sun on them is time-dependent. Nutation of the angular momentum axis of a planet is the resulting small, time-dependent motion of that axis in space and can be expressed as a sum of periodic terms, whose main periods are subharmonics of the orbital period of the planet (for the Earth, see Chapter 3.10). Other planets and satellites can also exert a torque on the planet and cause additional nutational motion, but these nutations are generally negligible with respect to those related to the solar torque, except for the Earth's nutations due to the Moon.

Equation [1] shows that the change in angular momentum is entirely due to the external torque and further does not depend on the interior of the planet. This suggests that nutation observations would have no geophysical interest, other than providing a value for the relative moment of inertia difference (J_2/C), in addition to but less precise than precession (see eqn [5] and also eqns [65] and [66]). However, observations do not measure orientation changes of the angular momentum axis but of the figure axis or the rotation axis of the mantle. In studies of periodic rotation variations, three different polar axes are distinguished: the rotation axis, the figure axis, and the angular momentum axis. The figure axis is defined as the axis of greatest moment of inertia, and the rotation axis is the axis of rotation of the solid outer part of the planet, that is, the mantle and crust, if the (outer) core is liquid. In general, the rotation and figure axes do not coincide with the angular momentum axis, and their orientations do depend on the interior of the planet. We will see that the relation between both axes and the angular momentum axis depends in a complex way on the interior and that nutation observations give direct access to the properties of the interior of a terrestrial planet.

To analyze the nutation of figure and rotation axes, it is more convenient to rewrite eqn [1] in a reference frame attached to the rotating planet. Let $\vec{e}_1, \vec{e}_2, \vec{e}_3$ represent three orthonormal vectors along corotating, body-fixed axes, rotating with instantaneous angular velocity $\vec{\omega}$ with respect to an inertial reference frame. We will choose the rotation axis to be close to the third axis. For both the inertial and the corotating reference frames, the center of mass of the planet is chosen as the origin O. For any vector $\vec{V}$, the time derivative with respect to the corotating reference frame is related to the time derivative with respect to the inertial reference frame as

$$\left.\frac{\mathrm{d}\vec{V}}{\mathrm{d}t}\right|\text{inertial} = \left.\frac{\mathrm{d}\vec{V}}{\mathrm{d}t}\right|\text{co}-\text{rotating} + \omega\times\vec{V} \qquad [6]$$

(e.g., Goldstein, 1950), and conservation eqn [1] can be expressed as

$$\frac{\mathrm{d}\vec{H}}{\mathrm{d}t} + \vec{\omega}\times\vec{H} = \vec{L} \qquad [7]$$

where the time derivative is with respect to the body-fixed reference frame.

The angular momentum vector can be written as an integral over the total volume V of the planet as

$$\vec{H} = \int_V \vec{r}\times\vec{v}\,\rho\,\mathrm{d}V \qquad [8]$$

where $\vec{r}$ is the coordinate vector, $\vec{v}$ the velocity, and ρ the density of the mass elements. For a rigid planet, we have

$$\vec{H} = \int_V \vec{r}\times\left(\vec{\omega}\times\vec{r}\right)\rho\,\mathrm{d}V \qquad [9]$$

which can, by introducing the inertia tensor $\mathbf{I}$ with components

$$I_{ij} = \int_V \left[\left(x_1^2+x_2^2+x_3^2\right)\delta_{ij} - x_i x_j\right]\rho\,\mathrm{d}V \qquad [10]$$

be written as

$$\vec{H} = \mathbf{I}\cdot\vec{\omega}\,. \qquad [11]$$

Here, x_i are the rectangular Cartesian coordinates of the mass elements. By a suitable choice of coordinate axes, the inertia tensor can be brought to diagonal form and the angular momentum components reduce to

$$\left.\begin{aligned} H_1 &= A\omega_1,\\ H_2 &= B\omega_2,\\ H_3 &= C\omega_3. \end{aligned}\right\} \qquad [12]$$

For principal axis rotation, it follows that the figure axis and the rotation axis coincide with the angular momentum axis for a rigid planet.

By substituting eqn [12] into eqn [7], we obtain Euler equations for a rigid planet:

$$A\frac{\mathrm{d}\omega_1}{\mathrm{d}t} + (C-B)\omega_2\omega_3 = L_1 \qquad [13]$$

$$B\frac{d\omega_2}{dt}+(A-C)\omega_1\omega_3=L_2 \quad [14]$$

$$C\frac{d\omega_3}{dt}+(B-A)\omega_1\omega_2=L_3 \quad [15]$$

For rapidly spinning planets like the Earth and Mars, deviations from spherical symmetry are dominated by the flattening induced by rotation, which is symmetrical about the mean rotation axis x_3, so that the approximation $A=B$ can be used. For the Earth, for example, the relative difference between A and B is more than 100 times smaller than the relative difference between A and C. In the absence of external torques $\vec{L}$, the solution of Euler equations can then be written as

$$\left.\begin{aligned}\omega_1&=a\cos(\sigma_E t+f),\\ \omega_2&=a\sin(\sigma_E t+f),\\ \omega_3&=\Omega,\end{aligned}\right\} \quad [16]$$

where a is the amplitude and f the phase of the free polar motion. The motion is said to be free since both the amplitude and the phase depend only on the initial conditions if dissipation is neglected. Given an initial deviation of the rotation axis from the figure axis, the rotation axis rotates, or wobbles, about the figure axis with the Euler frequency:

$$\sigma_E=\frac{C-A}{A}\Omega. \quad [17]$$

This Euler wobble is a manifestation of the conservation of angular momentum when the figure axis and the rotation axis do not coincide. Solution (Borderies, 1980) is an example of wobble or polar motion, which in general describes the orientation variations of the rotation axis with respect to a body-fixed polar axis (for more precise definitions of polar motion and wobble, see **Chapters 3.10** and **3.09**). Polar motion can also be forced by motion in fluid planetary layers, such as an atmosphere and oceans, by redistributing mass and carrying additional angular moment (see **Section 10.04.2**). These motions can also cause periodic variations in the ω_3-component of the rota vector or changes in the rotation speed. As these variations imply changes in the length of the day, they are, in the geophysical literature, mostly referred to as length-of-day variations (ΔLOD).

10.04.2.1.3 Kinematic relation between polar motion and nutation

To describe rotation variations in space, the body-fixed reference frame must be related to an inertial reference frame, which we here take to have coordinates x_1', x_2', x_3' and an origin at the mass center of the planet. The transformation is usually described in terms of three rotations over three Euler angles (see **Figure 1**). We introduce the Euler angle ψ from the x_1'-axis to the intersecting line (ascending node line) between the (x_1', x_2')-plane of the inertial reference frame and the equator of the body-fixed reference frame, the Euler angle ε from the inertial x_3'-axis to the normal to the planet's equator (x_3-axis), and the Euler angle ϕ from the node line to the x_1-axis. If the orbital plane is assumed to be fixed and to coincide with the (x_1', x_2')-plane, ψ is the precession angle, ε the obliquity, and ϕ the rotation angle. The time derivatives of the Euler angles represent combinations of rotations of the three body-fixed axes with respect to the inertial frame. The relation between

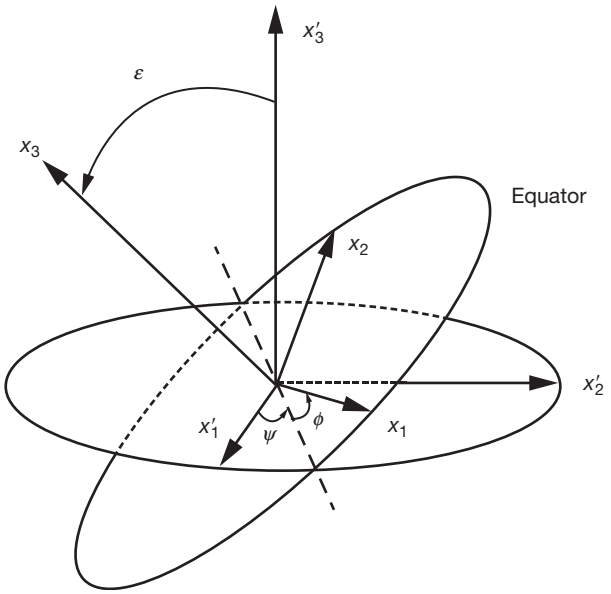

Figure 1 Euler angles.

the components (in the body frame) of the rotation vector and the time derivatives (in inertial space) of the Euler angles is given by Euler kinematic equations (e.g., Goldstein, 1950; Moritz and Mueller, 1987):

$$\left.\begin{aligned}\omega_1&=-\dot{\varepsilon}\cos\phi-\dot{\psi}\sin\varepsilon\sin\phi,\\ \omega_2&=\dot{\varepsilon}\sin\phi-\dot{\psi}\sin\varepsilon\cos\phi,\\ \omega_3&=\dot{\phi}+\dot{\psi}\cos\varepsilon.\end{aligned}\right\} \quad [18]$$

Because the figure axis is defined in terms of the planetary mass elements that rotate about the rotation axis, a variation in the rotation axis with respect to an inertial reference frame also leads to a variation in the figure axis with respect to the inertial reference frame. Moreover, these variations are not the same, and therefore, any periodic variation in the orientation of the rotation or figure axis in space (nutation) is accompanied by a periodic variation of the rotation axis with respect to the figure axis (polar motion or wobble), and vice versa. Consider, for example, the Euler wobble (eqn [16]). During the wobble, both the figure and the rotation axis have to change their orientation in inertial space; otherwise, the planet's spin angular momentum (which is defined in terms of the inertia and rotation of the planet; see eqn [11]) cannot be conserved. Mathematically, from the first two Euler kinematic equations (Bouquillon and Souchay, 1999), we have

$$\dot{\varepsilon}+i\sin\varepsilon\dot{\psi}=-\tilde{\omega}e^{i\phi} \quad [19]$$

where $\tilde{\omega}=\omega_1+\omega_2$ is the complex equatorial component of the rotation. If the x_3'-axis is chosen normal to the ecliptic at the time considered (the ecliptic of date) of the planet and the x_1'-axis points to the ascending node, $\dot{\varepsilon}$ and $\dot{\psi}$ represent changes in obliquity and in longitude (nutation). Equation [19] relates wobble described by the angle $\tilde{\omega}/\Omega$ to the time derivative of the nutation of the figure axis given by $\dot{\varepsilon}+i\sin\varepsilon\dot{\psi}$.. When the time dependence of ϕ is approximated by Ωt, periodic changes in the rotation vector with any forcing frequency σ in the corotating reference frame (wobble) are seen

to correspond to changes in longitude and obliquity (nutation) with frequency $\sigma' = \sigma + \Omega$ in the inertial reference frame.

By integrating eqn [19] with respect to time, it also follows that the amplitude of nutation of the figure axis differs a factor Ω/σ' from the amplitude of the wobble $(\tilde{\omega}/\Omega)$ of the rotation axis about the planet's figure axis. The motion of the rotation axis in space is the sum of the motion of the rotation axis about the figure axis (in Euler angles, $\delta_\varepsilon + i\sin\varepsilon\delta\psi = -i\tilde{\omega}\exp(i\Omega t)/\Omega$; see, e.g., Moritz and Mueller, 1987) and the motion of the figure axis in space. It then follows that the ratio of the amplitude of the wobble and the amplitude of nutation of the rotation axis is equal to σ'/σ. For the rapidly rotating planets, such as the Earth and Mars, the rotation period is much shorter than the orbital period. The main periods of nutation are related to the orbital motion and are therefore long compared to the rotation period $(\sigma'/\Omega \ll 1)$. Wobble periods are related to the seasons (and thus also to the orbital motion) and are therefore also long $(\sigma/\Omega \ll 1)$. The main nutations are therefore associated with very small wobble of diurnal period in the corotating reference frame, and large polar motion is associated with very small nutation of the rotation axis that is of diurnal period in space. When observations have limited time resolution, averaged orientations can only be obtained, and the small diurnal contributions to polar motion and nutation are neglected. For the Earth, the convention is to introduce an intermediate polar axis that only has low-frequency nutational motion in space and to define polar motion as the motion of that axis in the terrestrial reference frame outside the retrograde diurnal frequency band (e.g., Chapter 3.10). Each phenomenon can then be studied separately. Polar motion has been described before as the motion of the rotation axis about the figure axis, but actually, we see that the rotation axis remains nearly fixed with respect to inertial space. It is the figure axis, or the planet itself, that wobbles about the rotation axis.

10.04.2.2 Liouville Equations

10.04.2.2.1 Excitation

Both external and internal processes can excite periodic rotation variations of a terrestrial planet. We have sufficient knowledge about the external gravitational causes, but other processes are more difficult to model. For example, the seasonal global CO_2 exchange between the Martian atmosphere and the polar caps causes variations in the length of day of Mars, but is not precisely known. By studying rotation variations of a terrestrial planet, more can thus be learned about the excitation processes. Moreover, as the rotational response depends on the planet's structure and composition, also insight into the planetary interior can be obtained. This is particularly so for the rotation variations due to well-known external gravitational causes, such as for the nutations of Mars and the libration of Mercury.

10.04.2.2.2 Basic equations

Basic to most geophysical studies of the rotation of the Earth are the Liouville equations, which describe the change in angular momentum $\vec{H}$ of the deformable planet due to an applied torque (see, e.g., Chapter 3.10). These equations are also an ideal tool for investigating the rotation of the other terrestrial planets. We use a corotating reference frame as before. As a terrestrial planet is not rigid, we consider the three coordinate axes to be along the mean axes of principal moments of inertia of the mantle and to rotate with instantaneous angular velocity $\vec{\omega}$ with respect to an inertial reference frame. In equilibrium, the planet is assumed to rotate uniformly with angular velocity $\vec{\omega} = \Omega\vec{e}_3$.. Due to internal and external excitations, the rotation velocity of the mantle

$$\vec{\omega} = \Omega \begin{pmatrix} m_1 \\ m_2 \\ 1 + , m_3 \end{pmatrix} \qquad [20]$$

deviates from the equilibrium rotation velocity aligned with the polar axis. The small deviations m_1 and m_2 describe wobble, and m_3 gives LOD variations.

In the reference frame rotating with the instantaneous rotation vector of the mantle, the change in angular momentum of the planet is governed by eqn [7]. The angular momentum (eqn [8]) can be expressed as

$$\vec{H} = \mathbf{I}\cdot\vec{\omega} + \vec{h} \qquad [21]$$

where

$$\mathbf{I} = \begin{pmatrix} A & 0 & 0 \\ 0 & B & 0 \\ 0 & 0 & C \end{pmatrix} + (c_{ij}). \qquad [22]$$

Mass redistribution and deformation of the planet cause small increments in inertia c_{ij}, and the small relative angular momentum $\vec{h}$ is due to relative motion with respect to the corotating frame in the fluid parts of the planet (liquid core, oceans, and atmosphere). We assume here that there is no rotation in the deformation field of the mantle $\left(\vec{h}^{\text{mantle}} = 0\right)$ with respect to the reference frame of the planet. The axes are then called mantle Tisserand axes (Moritz and Mueller, 1987; Munk and MacDonald, 1960). Equation [21] shows that part of the angular momentum is absorbed in relative motion, such as relative motion of a liquid core, and in perturbations of the moment of inertia. Rotation variations for a deformable planet are therefore different from those of a rigid planet. Deformations tend to decrease the rotation variations. A rotationally decoupled liquid core, on the other hand, may lead to larger mantle rotation variations because the mantle has a smaller moment of inertia than the total planet. By using eqns [20]–[22], the three components of the Liouville equations for the whole planet can be expressed as

$$A\Omega\dot{m}_1 + \Omega^2(C-B)m_2 = L_1 - \Omega\dot{c}_{13} + \Omega^2 c_{23} - \dot{h}_1 + \Omega h_2 \qquad [23]$$

$$B\Omega\dot{m}_2 + \Omega^2(C-A)m_1 = L_2 - \Omega\dot{c}_{23} + \Omega^2 c_{13} - \dot{h}_2 + \Omega h_1 \qquad [24]$$

$$C\Omega\dot{m}_3 = L_3 - \Omega\dot{c}_{33} - \dot{h}_3 \qquad [25]$$

These equations are linearized in m_i and c_{ij}, as these quantities are very small compared to their leading order terms in the equations. A particular consequence of this approximation is that there is no term in B – A in eqn [25], because that term is of second order in the rotation variations (e.g., Hinderer et al., 1982). Furthermore, the first two equations decouple from the third equation. Therefore, wobble and LOD variations are decoupled and can be calculated separately. The symmetry between eqn [25] on the one hand and eqns [23] and [24]

on the other hand is broken because the planet's mean rotation introduces a preferred direction, which we have chosen to be along the x_3-axis.

The right-hand sides of eqns [23]–[25] describe the excitations: external torques (Agnor et al., 1999), mass redistribution (Aharonson et al., 2004), and relative motion (Anderson, 1989). Of these, the external torque can most precisely be determined. The mass redistribution and relative motion on the other hand do depend not only on the excitation process but also on the rotation variations, as we will see later. The right-hand sides of eqns [23]–[25] divided by $\Omega\ (C-A)$ are called the excitation functions (Munk and MacDonald, 1960).

For rapidly rotating planets, the equatorial flattening (due to nonhydrostatic effects) is much smaller than the polar flattening (mainly due to the fast rotation), so the approximation $A=B$ can be used in the Liouville equations. By introducing the complex notation

$$\begin{aligned}\tilde{m}&=m_1+\mathrm{i}m_2\\ \tilde{c}&=c_{13}+\mathrm{i}c_{23}\\ \tilde{h}&=h_1+\mathrm{i}h_2\end{aligned} \qquad [26]$$

wobble can be described by the complex sum of the first two components of the Liouville eqns [23] and [24]:

$$A\Omega\dot{\tilde{m}}-\mathrm{i}(C-A)\Omega^2\tilde{m}=-\Omega\dot{\tilde{c}}-\mathrm{i}\Omega^2\tilde{c}+\dot{\tilde{h}}-\mathrm{i}\Omega\tilde{h} \qquad [27]$$

If the planet's core is liquid, Hough (1895) (see also Poincaré, 1910) showed with mathematical rigor that a change in the mantle rotation leads to a change in the core flow that can be expressed as a sum of two terms: a rigid body rotation of the core, which is of the same order of magnitude as the mantle rotation change, and an irrotational core flow, which is one order in the core flattening smaller. This result was derived for an incompressible, inviscid, and homogeneous core, but further studies showed it to be a valid approximation when these conditions are relaxed (see, e.g., Busse, 1968; Roberts and Stewartson, 1965; Stewartson and Roberts, 1963 for viscosity, and Smith, 1977 for a numerical investigation of the problem).

Three additional quantities m_i^{f}, describing the relative rotation of the fluid core with respect to the mantle, have to be determined when the planet's core is liquid. We define these by

$$\vec{\omega}^{\mathrm{f}}=\Omega\begin{pmatrix}m_1^{\mathrm{f}}\\ m_2^{\mathrm{f}}\\ m_3^{\mathrm{f}}\end{pmatrix}. \qquad [28]$$

The total rotation vector of the core is then $\vec{\omega}+\vec{\omega}^{\mathrm{f}}$. It is assumed here that the core corotates with the mantle in the equilibrium state. The differential rotations of the core are determined by three additional Liouville equations, which express the rate of change of angular momentum of the core as a result of the torque $\vec{L}$ exerted on the core in the same mantle corotating reference frame as before:

$$\frac{\mathrm{d}\vec{H}^{\mathrm{f}}}{\mathrm{d}t}+\vec{\omega}\times\vec{H}^{\mathrm{f}}=\vec{L}^{\mathrm{f}} \qquad [29]$$

where

$$\vec{H}^{\mathrm{f}}=\mathbf{I}^{\mathrm{f}}\cdot\vec{\omega}+\vec{h}^{\mathrm{f}} \qquad [30]$$

$$\begin{aligned}&=\Omega\left[\begin{pmatrix}A^{\mathrm{f}}&0&0\\0&B^{\mathrm{f}}&0\\0&0&C^{\mathrm{f}}\end{pmatrix}+\begin{pmatrix}c_{ij}^{\mathrm{f}}\end{pmatrix}\right]\\ &\times\begin{pmatrix}m_1\\ m_2\\ 1+m_3\end{pmatrix}+\begin{pmatrix}A^{\mathrm{f}}m_1^{\mathrm{f}}\\ B^{\mathrm{f}}m_2^{\mathrm{f}}\\ C^{\mathrm{f}}m_3^{\mathrm{f}}\end{pmatrix},\end{aligned} \qquad [31]$$

and $A^{\mathrm{f}}<B^{\mathrm{f}}<C^{\mathrm{f}}$ are the three principal moments of inertia of the fluid core and c_{ij}^{f} the small increments in the inertia of the core. The three components of the Liouville equations for the liquid core can then be written as

$$\begin{aligned}&A^{\mathrm{f}}\Omega\left(\dot{m}_1+\dot{m}_1^{\mathrm{f}}\right)-B^{\mathrm{f}}\Omega^2m_2^{\mathrm{f}}+\Omega^2\left(C^{\mathrm{f}}-B^{\mathrm{f}}\right)m_2+\Omega\dot{c}_{13}^{\mathrm{f}}-\Omega^2c_{23}^{\mathrm{f}}\\ &=L_1^{\mathrm{f}}\end{aligned} \qquad [32]$$

$$\begin{aligned}&B^{\mathrm{f}}\Omega\left(\dot{m}_2+\dot{m}_2^{\mathrm{f}}\right)-A^{\mathrm{f}}\Omega^2m_1^{\mathrm{f}}+\Omega^2\left(C^{\mathrm{f}}-A^{\mathrm{f}}\right)m_1+\Omega\dot{c}_{23}^{\mathrm{f}}-\Omega^2c_{13}^{\mathrm{f}}\\ &=L_2^{\mathrm{f}},\end{aligned} \qquad [33]$$

$$C^{\mathrm{f}}\Omega\left(\dot{m}_3+\dot{m}_3^{\mathrm{f}}\right)+\dot{c}_{33}^{\mathrm{f}}=L_3^{\mathrm{f}}, \qquad [34]$$

where only terms linear in m_i, m_i^{f}, c_{ij}, and c_{ij}^{f} were retained. As for the Liouville equations for the whole planet, the rotation rate variations are decoupled from the orientation variations, and there is no term in $B^{\mathrm{f}}-A^{\mathrm{f}}$ in eqn [34]. To obtain the solutions for wobble (m_x and m_y) and LOD variations (m_z) of a planet with a liquid core, the deformation-induced incremental inertia terms ($c_{13}, c_{23}, c_{13}^{\mathrm{f}}, c_{23}^{\mathrm{f}}, c_{33}, c_{33}^{\mathrm{f}}$), the relative angular momentum (h_1, h_2, h_3), and the torques ($L_1, L_2, L_3, L_1^{\mathrm{f}}$, and L_3^{f}) have to be determined from the excitation processes considered. For every frequency σ, the associated nutations of the rotation axis have an amplitude differing a factor σ/σ' as follows from integrating Euler's kinematic eqn [19] with respect to time.

10.04.2.2.3 Core–mantle coupling

The torque on the fluid core is the sum of the external gravitational torque on the permanent core figure due to the Sun and other solar system bodies and the torque due to the mantle. The latter torque includes viscous coupling between the mantle and the core, electromagnetic coupling, gravitational coupling, pressure coupling due to the ellipsoidal core form, and pressure coupling due to topography on the CMB (core–mantle boundary). By assuming the dissipative torques (viscous and electromagnetic) to be negligibly small for relatively short-period rotation variations (but see **Section 10.04.2.4** for their effect on the long-term rotation) and by neglecting CMB topography other than the ellipticity, the torque on the fluid core is often written as the sum of the external gravitational torque $\left(\vec{L}_{\mathrm{ext}}^{\mathrm{f}}\right)$ and the so-called inertial torque $\left(\vec{N}\right)$, which is the sum of the gravitational and pressure torque. By using the Navier–Stokes equation for the fluid core, the inertial torque can be calculated by assuming a Poincaré flow in the fluid core. Correct up to the first order in the flattenings and the rotation variations, we have

$$\begin{aligned}N_1&=-L_{\mathrm{ext},1}^{\mathrm{f}}+\Omega^2\left(C^{\mathrm{f}}-B^{\mathrm{f}}\right)\left(m_2+m_2^{\mathrm{f}}\right)-\Omega^2c_{23}^{\mathrm{f}}\\ N_2&=-L_{\mathrm{ext},2}^{\mathrm{f}}+\Omega^2\left(A^{\mathrm{f}}-C^{\mathrm{f}}\right)\left(m_1+m_2^{\mathrm{f}}\right)-\Omega^2c_{13}^{\mathrm{f}}\\ N_3&=-L_{\mathrm{ext},3}^{\mathrm{f}}\end{aligned} \qquad [35]$$

(e.g., Rochester, 1976; Sasao et al., 1977, 1980; and Hinderer et al., 1982; Van Hoolst and Dehant, 2002 for the triaxial case).

By substituting these expressions into Liouville eqns [32]–[34] for the core, we have

$$\frac{\mathrm{d}\vec{H}^{\mathrm{f}}}{\mathrm{d}t}-\vec{\omega}^{\mathrm{f}}\times\vec{H}^{\mathrm{f}}=0 \qquad [36]$$

(Mathews et al., 1991; Sasao et al., 1980). From the expression (Chapman and Lindzen, 1970) for the third component of the inertial torque, it follows that $L_3^{\mathrm{f}}=0$ and

$$C^{\mathrm{f}}\Omega\left(\dot{m}_3+\dot{m}_3^{\mathrm{f}}\right)+\dot{c}_{33}^{\mathrm{f}}\Omega=0. \qquad [37]$$

If deformation is neglected, there is no net change in the third component of the angular momentum of the core in the lowest-order approximation in the rotation variations and the flattenings: the external torque is balanced by the core–mantle coupling mechanisms for the third component. For an incompressible, inviscid, and homogeneous core, Hough (1895) already demonstrated that the additional core rotation with respect to the equilibrium rotation is purely equatorial, so that the rotation rate of the core remains constant. There is no complete torque balance for the equatorial components. Again, this symmetry breaking between the axial and the equatorial components is due to the mean rotation of the planet, which introduces a preferred direction in the problem.

10.04.2.2.4 Mass redistribution

We now discuss the problem of determining the incremental inertia terms. In particular, we consider the interesting case of excitation by an atmosphere as a typical example that includes excitation due to both relative motion and mass redistribution. By setting the external torque equal to zero and introducing the equatorial angular momentum function $\tilde{\chi}=\frac{\Omega\tilde{c}+\tilde{h}}{(C-A)\Omega}$ and the axial angular momentum function $\chi_3=\frac{\Omega c_{33}+h_3}{c\Omega}$, the Liouville equations [27] and [25] can be reexpressed as

$$\tilde{m}+\frac{\mathrm{i}}{\sigma E}\frac{\mathrm{d}\tilde{m}}{\mathrm{d}t}=\tilde{\chi}-\frac{\mathrm{i}}{\Omega}\frac{\mathrm{d}\tilde{\chi}}{\mathrm{d}t}, \qquad [38]$$

$$\dot{m}_3=-\dot{\chi}_3. \qquad [39]$$

The contribution of the atmosphere to the angular momentum functions can be separated in a term due to the wind ($\tilde{h}$ and h_3) and a term due to the atmospheric mass ($\tilde{c}$ and c_{33}). Explicit expressions for these 'wind' and 'matter' atmospheric angular momentum functions in terms of wind velocity and atmospheric pressure can be found in, for example, Barnes et al. (1983). For a rigid planet, only the atmospheric wind angular momentum functions, $\tilde{\chi}_{\mathrm{A}}^{\mathrm{W}}$ and $\chi_{3,\mathrm{A}}^{\mathrm{W}}$, and atmospheric matter angular momentum functions, $\tilde{\chi}_{\mathrm{A}}^{\mathrm{W}}$ and $\chi_{3,\mathrm{A}}^{\mathrm{M}}$, have to be considered in the Liouville eqns [38] and [39]. The superscript A denotes that only the direct contribution from the atmosphere (and seasonal polar caps) is considered, and superscripts M and W indicate matter and wind terms, respectively.

For an entirely solid but nonrigid planet, contribution to the angular momentum functions from the incremental inertia terms $\tilde{c}=c_{13}+\mathrm{i}c_{23}$ and c_{33} due to the planet's response has to be added. Two effects contribute to these inertia terms. First, when the rotation vector of the planet changes, the centrifugal potential changes and induces a slight mass redistribution of the planet. The associated changes in the inertia terms (indicated by superscript 'center') can for any planet be determined from McCullagh's theorem:

$$\tilde{c}^{\mathrm{center}}=k_2\frac{\Omega^2R^5}{3G}\tilde{m}, \qquad [40]$$

$$c_{33}^{\mathrm{center}}=k_2\frac{4R^5\Omega^2}{9G}m_3, \qquad [41]$$

where k_2 is the potential Love number of degree 2 of the planet (Moritz and Mueller, 1987; Munk and MacDonald, 1960). These contributions to the inertia terms are independent of the excitation source.

A second contribution to the incremental inertia terms $\tilde{c}$ and c_{33} is due to the atmosphere (and ice cap) loading. The loading induces a deformation and a corresponding change in the mass distribution of the planet. The associated change in the planetary gravitational potential at the planet's surface is most conveniently expressed as k_2' times the potential of the load, where k_2' is the degree-two load Love number (Munk and MacDonald, 1960). Since the incremental moments of inertia associated with the change in gravitational potential due to the atmospheric loading are linearly proportional to the change in the gravitational potential according to McCullagh's theorem, it follows that the contribution of the loading effect is $k_2'\tilde{\chi}_{\mathrm{A}}^{\mathrm{M}}$ to the equatorial angular momentum function and $k_2'\chi_{3,\mathrm{A}}^{\mathrm{M}}$ to the axial angular momentum function.

10.04.2.2.5 Periodic rotation variations

By taking the mass redistribution into account and solving eqns [38] and [39] at a given frequency σ, wobble of a deformable solid planet can be expressed as

$$\tilde{m}(\sigma)=-\frac{\alpha(\sigma+\Omega)}{(\sigma-\sigma c w)}\left[\left(1-k_2'\right)\tilde{\chi}_{\mathrm{A}}^{\mathrm{M}}(\sigma)+\tilde{\chi}_{\mathrm{A}}^{\mathrm{W}}(\sigma)\right], \qquad [42]$$

(e.g., Moritz and Mueller, 1987), and relative rotation rate variations are given by

$$m_3(\sigma)=-\left[\left(1+k_2'\right)\chi_{3,\mathrm{A}}^{\mathrm{M}}(\sigma)+\chi_{3,\mathrm{A}}^{\mathrm{W}}(\sigma)\right]\times\left(1+k_2\frac{4R^5\Omega^2}{9GC}\right)^{-1}. \qquad [43]$$

Here,

$$\alpha=\frac{C-\frac{A+B}{2}}{\frac{A+B}{2}} \qquad [44]$$

is the dynamic polar flattening. The only differences with respect to a solid planet are the term in the loading Love number k_2', and the change from the Euler frequency σ_{E} to the frequency σ_{CW} of the Chandler wobble (CW), which is the extension of the Euler wobble to a deformable planet (see also eqn [47] later). The difference between the CW frequency and the Euler frequency is due to the deformation of the planet as a result of the change in the centrifugal potential associated with the wobble.

For planets with a liquid core, the rotation rate variations differ only by a factor C/C^{m}, where C^{m} is the polar moment of inertia of the mantle, with respect to a solid planet:

$$m_3(\sigma)=-\frac{C}{C^{\mathrm{m}}}\left[\left(1+k_2'\right)\chi_{3,\mathrm{A}}^{\mathrm{M}}(\sigma)+\chi_{3,\mathrm{A}}^{\mathrm{W}}(\sigma)\right] \qquad [45]$$

when the small inertia terms due to the centrifugal force are neglected. These terms describe the additional variation in rotation rate due to the changes in the polar moment of inertia resulting from the rotation rate variations and are a second-order effect.

For polar motion of planets with a liquid core, the incremental inertia terms $\tilde{c}^{f} = c^{f}_{13} + \mathrm{i}c^{f}_{23}$ and c^{f}_{33} do have to be determined. The main reason is that for polar motion, changes in the inertia tensor are compared to differences in the moments of inertia (see eqns [23], [24], [32], and [33]), and for rotation rate variations, they are compared to the polar moment of inertia C itself (see eqns [25] and [34]), which is several orders of magnitude larger than the differences in principal moments of inertia for the terrestrial planets. The incremental core inertia terms can be expressed in terms of compliances or generalized Love numbers (**Chapter 3.10**; Dehant et al., 1993; Hinderer et al., 1982; Mathews et al., 1991; Sasao et al., 1977, 1980). By solving the Liouville equations for the entire planet and the liquid core, wobble can then be expressed as

$$\tilde{m}(\sigma) = -\frac{\alpha A(\sigma-\Omega)}{A^{m}(\sigma-\sigma cw)}\left(1+\frac{A^{f}}{A}\frac{\sigma'}{\sigma'-\sigma'_{FCN}}\right) \times\left[\left(1+k'_{2}\right)\tilde{\chi}^{M}_{A}(\sigma)\tilde{\chi}^{W}_{A}(\sigma)\right] \quad [46]$$

(Defraigne et al., 2000; Sasao et al., 1980), where A^{m} is the equatorial moment of inertia of the mantle with respect to the first body-fixed axis. Here, σ_{cw} and σ'_{FCN} are the frequencies of the CW and the free core nutation (FCN). These normal modes can be determined by solving the Liouville equations in the case of no internal or external excitation. The CW consists essentially of a rigid rotation of the mantle about the mantle rotation axis. The FCN is mainly a rigid rotation of the fluid core about the mean mantle rotation axis and only exists when the core is liquid. As they are defined in the absence of external excitation, the normal modes conserve the total spin angular momentum of the planet. Both the CW and the FCN have their origin in the flattening of the planet. The frequencies of the CW and the FCN can, correct up to the first order in the flattenings, be expressed as (**Chapter 3.10**; Sasao et al., 1980; Van Hoolst and Dehant, 2002; Yoder and Standish, 1997)

$$\sigma_{cw} = \Omega\frac{A}{A^{m}}\sqrt{\left(1-\frac{k_{2}}{k}\right)^{2}\alpha^{2}-\frac{\beta^{2}}{4}} \quad [47]$$

$$\sigma'_{FCN} = -\Omega(\alpha_{f}-\beta_{d})A/A_{m} \quad [48]$$

where $k = 3\,J_{2}/q_{0}$ is the secular Love number, α_{f} the dynamic polar flattening at the CMB, and β_{d} a compliance that describes the deformations due to the centrifugal effect of the differential wobble of the core. We also used the equatorial flattening

$$\beta = \frac{B-A}{A} \quad [49]$$

and the ratio of the surface centrifugal acceleration to the surface gravity

$$q_{0} = \frac{\Omega^{2}R^{3}}{GM}. \quad [50]$$

Note that the frequency of the FCN in eqn [48], as indicated by the prime, is expressed with respect to the inertial reference frame and that the CW frequency in eqn [47] is given in the body-fixed reference frame. As the flattenings are small for terrestrial planets, both these periods are long compared to the rotation period of the planet. Note, however, that the CW period is long in a corotating reference frame and that the FCN has a long period with respect to an inertial reference frame. Equations [47] and [48] show that deformation ($k_{2} > 0$ and $\beta_{d} > 0$) lengthens the CW and FCN periods and that a liquid core decreases the CW period.

Solutions [42] and [46] for wobble of a solid planet and a planet with a liquid core show resonances at the frequencies of the CW and the FCN. These normal modes of the planet are characterized by a predominant rotational motion and are sometimes called rotational normal modes. In general, the rotational response of a planet to an external forcing can be expressed as a linear combination of the planet's normal eigenfunctions, which form a complete set (Wahr, 1981a,b). Although the largest – and most familiar – class of normal modes is the set of seismic modes, the rotational normal modes are more important for the description and understanding of planetary rotation variations. The seismic modes have very small rotation in their displacement field and therefore cannot appreciably affect the rotation of a planet. They also have much smaller periods than the periods at which rotation variations are excited. For the Earth, the seismic mode with the longest period is the so-called football mode, with a period of 53.9 min (Dahlen and Tromp, 1998). Most other modes have periods of the order of minutes or tens of minutes. The three other terrestrial planets are smaller and less dense, and, being of similar structure, their seismic periods are smaller. As an example, for Mars, the football mode has a period of about 30 min (Gudkova and Zharkov, 2004; Van Hoolst et al., 2000a). As the rotational forcing frequencies are far from the frequencies of the seismic normal modes, there are no resonance effects with these modes.

Four rotational normal modes mainly related to orientation changes can be distinguished for terrestrial planets with at most three different internal layers that can show relative rotation (solid mantle + crust, liquid outer core, and solid inner core): the CW, the FCN, the inner core wobble (ICW), and the free inner core nutation (FICN). The ICW is analogous to the CW and describes the relative rotation of the figure axis of the inner core about the mantle rotation axis. The FICN represents the relative rotation of the inner core about the mantle rotation axis. The ICW has a long period in a corotating frame and the FICN a long period in an inertial frame. Extended Liouville theories for terrestrial planets with a solid elastic mantle, a liquid outer core, and an elastic inner core show that the solution for polar motion shows resonances at the eigenfrequencies of these four rotational normal modes (see, e.g., Dehant et al., 1993, 2005; Mathews et al., 1991, 2002). An important consequence of these resonances is that for frequencies close to the resonant frequencies, rotation variations can be amplified. The detection of the amplification yields information on the normal mode frequencies and thus on the internal properties on which these frequencies depend (see, e.g., eqns [47] and [48]).

10.04.2.3 Hamiltonian Equations and Long-Term Evolution

In astronomical studies of planetary rotation variations in which the planets are considered to be rigid (as opposed to

geophysical studies), Hamiltonian and Lagrangian approaches are customarily used (Kinoshita, 1977; Smart, 1953). These methods have also been extended to include effects of deformation and core–mantle coupling for the nutations of the Earth (see, e.g., Getino and Ferrándiz, 2000) but have not yet reached that level of precision for the short-term variations in the rotation of the other terrestrial planets. On the other hand, for studies of the long-term evolution of planetary spins, Hamiltonian and Lagrangian equations are often preferred to torque equations. Hence, we here briefly introduce the Hamiltonian approach to planetary rotation in the frame of long-term changes of rotation.

For the long-term rotational evolution, it is customary to neglect polar motion and nutation and to assume that the terrestrial planets rotate about their greatest principal inertia axis, corresponding to the lowest rotational energy, and that the angular momentum axis also coincides with that axis, as would be the case for a rigid planet with principal axis rotation. These assumptions are justified since polar motion and nutation are very small compared to the long-term changes (see **Sections 10.04.3, 10.04.4**, and **10.04.5**) and average to zero over a sufficiently long time. Moreover, large wobble at any moment in the history of a planet will be damped in a relatively short time compared to the age of the solar system (Peale, 1976a; Yoder and Ward, 1979). Nevertheless, the terrestrial planets most likely all have had periods of large polar wander when the solid surface of the planet reorients with respect to the rotation axis as a result of mass redistribution due to internal or external causes that drives the planet to a new state of minimum energy corresponding to principal axis rotation (Gold, 1955; Matsuyama et al., 2006; Willemann, 1984). For example, large polar wander of a few 10° is thought to be caused by the emplacement of Tharsis (Matsuyama and Manga, 2010; see also Zhong, 2009).

Basic to the Hamiltonian and Lagrangian methods is the development of expressions for the kinetic energy and potential energy of the rotating planet interacting with other solar system bodies. The rotational kinetic energy T of a planet supposed rigid is given by

$$T=\frac{1}{2}\left(A\omega_1^2+B\omega_2^2+C\omega_3^2\right) \qquad [51]$$

when planetary effects on the orbit are neglected (see, e.g., Goldstein, 1950). The components of the angular velocity $\vec{\omega}$ are defined with respect to the principal axes of inertia of the planet. The potential energy of an isolated rigid body does not change with time and can therefore be neglected. The only potential energy to be included then is that due to the gravitational interaction with the Sun, the other planets, and satellites. By retaining only the degree-two terms of eqn [2], the potential energy U for an interacting body with mass M^* can be expressed as

$$U=-\frac{GMM^*}{r}-\frac{GMM^*}{2r^3}(A+B+C-3\mathcal{I}), \qquad [52]$$

where $\mathcal{I}$ is the moment of the inertia of the planet with respect to the direction from the planet's mass center to the perturbing body.

In the Lagrangian equations,

$$\frac{d}{dt}\left(\frac{\partial\mathcal{L}}{\partial\dot{q}_n}\right)-\frac{\partial\mathcal{L}}{\partial q_n}=0, \qquad [53]$$

where $\mathcal{L}=T-U$ is the Lagrangian and the Euler angles are taken as the generalized coordinates q_n. By using eqn [18], the kinetic energy can readily be expressed in terms of the time derivatives of the Euler angles. For Hamiltonian equations, the Euler angles and their adjoint moments could be used. However, these moments have no intuitive physical meaning, and often Andoyer variables are preferred (Andoyer, 1923; Kinoshita, 1977). For the case of principal axis rotation, the problem is reduced from six variables to four variables (Kinoshita, 1977). The two Andoyer variables to be used are (Agnor et al., 1999) the angular momentum amplitude $H=C\omega$ and (Aharonson et al., 2004) the angular momentum component normal to the orbital plane of date, $X=H\cos\varepsilon$, and the two conjugate Andoyer variables are (Agnor et al., 1999) the hour angle θ between the vernal equinox of date and a fixed direction in the equator (e.g., the axis of minimum moment of inertia) and (Aharonson et al., 2004) the precession ψ (in general, taking into account the motion of the orbit: see, e.g., Kinoshita, 1977). In addition to the hour angle, the Hamiltonian also depends on a second fast variable describing the revolution of the planet around the Sun. For studies of the long-term evolution of the planet, the Hamiltonian is averaged over these fast angles. For a rigid planet with principal axis rotation and without planetary perturbations and spin–orbit resonances, the resulting averaged Hamiltonian can be expressed as

$$\mathcal{H}_{\text{averaged}}=\frac{H^2}{2C}-\frac{\alpha_P}{2}\frac{X^2}{H} \qquad [54]$$

(see, e.g., Néron de Surgy and Laskar, 1997), where α_P is the precession constant (eqn [5]), and the Hamiltonian equations yield

$$\left.\begin{aligned}\frac{dH}{dt}&=0\\ \frac{dX}{dt}&=0\\ \frac{d\theta}{dt}&=\frac{H}{C}+\frac{a_P}{2}\frac{X^2}{H^2}\\ \frac{d\psi}{dt}&=\alpha_P\frac{X}{H}\end{aligned}\right\} \qquad [55]$$

Within the approximations made, it follows that the rotation speed of the planet, the obliquity, and the precession rate are constant in time.

In the case of spin–orbit resonances, that is, when the ratio of the rotation speed ω and the mean motion n approximates a rational number $p=\text{integer}/2$, combinations $\theta-pM$ of the two fast variables (M is the mean anomaly) appearing in the Hamiltonian cease to be fast variable and cannot be eliminated by the averaging procedure. The Andoyer variables H and X, or equivalently the rotation speed and the obliquity, then become time-dependent, with time derivatives being proportional to $\sin2(\theta-pM)$, and the spin–orbit resonances also contribute a term to the precession (see, e.g., Correia et al., 2003). For Mercury, the resulting changes in rotation speed (librations), obliquity variations, and precession rate will be studied in **Section 10.04.5**.

Additional effects can be taken into account by adding the corresponding energy to the Hamiltonian. Effects related to dissipative processes will be studied in **Section 10.04.2.4**. Here, we briefly consider the inclusion of planetary perturbations. Because the ecliptic of date, with respect to which the Andoyer variables are defined, changes its orientation due to planetary gravitational effects, additional terms have to be added to the Hamiltonian equations (eqn [55]) for X and ψ (e.g., Néron de Surgy and Laskar, 1997; Peale, 1973). The indirect effects of the other planets on the orbit are much more important than the direct planetary gravitational torque on the planet. As mentioned earlier, the direct torque is usually neglected, and so H remains constant. Planetary effects alone therefore do not affect the rotation rate of a planet on a long timescale, but can change the obliquity and precession. As will be discussed in **Section 10.04.5** on Mercury, planetary perturbations on the orbit can also periodically change the rotation rate on short timescales by indirectly modifying the solar torque.

If the spin axis of a terrestrial planet were fixed in inertial space, obliquity variations would be entirely due to the planetary-induced variations in the orientation of the orbital plane (called orbital precession as the normal to the orbital plane precesses about its mean orientation). However, the solar torque (and also the lunar torque for the Earth) on the flattened planet causes the planet to precess about the changing orbit normal. The resulting motion of the spin axis with respect to the orbit normal depends critically on the ratio of the precession period to the period of the orbital precession. For a very small ratio, the spin axis precession is about the slowly moving orbit normal and tracks that motion efficiently such that the obliquity is nearly constant. On the other hand, if the precession of the spin axis is much slower than the precession of the orbit, the spin axis will precess about the averaged orbit normal (see, e.g., Ward, 1992). If the ratio is about one (as is now the case for Mars), we have a resonant situation, and the obliquity variations can be large and chaotic (e.g., Touma and Wisdom, 1993; Ward, 1974). Laskar and Robutel (1993) have shown that the four terrestrial planets could have experienced large chaotic variations in obliquity during some period(s) of their history and that their obliquities cannot be considered as primordial.

10.04.2.4 Dissipative Effects as Causes of Secular Rotation Variations

10.04.2.4.1 Gravitational tides

Dissipation of tidal energy in the Earth is the principal cause of the secular increase in the length of day (Munk and MacDonald, 1960). Deviations from perfect elasticity of the planetary material delay the response of the planet to an applied tidal torque and cause the tidal bulge to be slightly misaligned with respect to the direction to the body raising the tides. The misalignment results in a small torque on the planet that alters the rotation of the planet. The theory of tides and the influence on the rotation and orbits of planets and satellites have been described in many books and review articles and will not be repeated here in detail (see, e.g., Darwin, 1908; Goldreich and Soter, 1966; Kaula, 1964; Lambeck, 1980; MacDonald, 1964; Melchior, 1983; Munk and MacDonald, 1960; Murray and Dermott, 1999). An important property is that the main part of the tidal potential is proportional to r^{-3} (see the degree-two part of eqn [2]), where r is the distance between the planet and the tide-raising body. Therefore, the tidal bulge is also proportional to r^{-3}. Since the gravitational torque on the planet is also proportional to r^{-3} (eqn [4]), the tidal torque is then proportional to r^{-6}. As for the Earth, the solar tidal torque slows down the rotation of a rapidly rotating terrestrial planet ($\omega > n$ or $\omega < -n$) since then the tidal bulge leads the planet–Sun direction when measured in the sense of rotation of the planet.

Because of the strong dependence on the distance to the Sun, tidal braking due to the Sun is much more efficient for Mercury and Venus than for the Earth and Mars and could be the cause of the slow rotation of Mercury and Venus compared to the fast rotation of the Earth and Mars. From eqn [1] and a tidal torque of magnitude

$$L_{\mathrm{T}} = \frac{3k_2 GM_{\odot}^2 R^5}{2a^6} \sin 2\delta \qquad [56]$$

for a circular orbit and zero obliquity (e.g., MacDonald, 1964; Murray and Dermott, 1999), the rate of decrease of rotation velocity can be approximated by

$$\frac{\mathrm{d}\omega}{\mathrm{d}t} = -\frac{3k_2 GM_{\odot}^2 R^5}{2Ca^6 Q}, \qquad [57]$$

where $Q \approx 1/(2\delta)$ is the dissipation or quality factor of the planet and δ the geometric lag angle between the tidal bulge and the line planet–Sun (the factor 2 stems from the fact that the main tides are semidiurnal with frequency 2ω for rapid rotators). The despin timescale t from fast initial rotation ($\omega \gg n$) to a rotation period commensurate with the orbital period ($\omega \sim n$) can be approximated by

$$\tau = \frac{2Ca^6 Q\omega_{\mathrm{initial}}}{3k_2 GM_{\odot}^2 R^5} \qquad [58]$$

As a result of the strong distance dependence ($\tau \propto a^6$), Mercury and Venus can despin within the age of the solar system, whereas Mars cannot (Goldreich and Soter, 1966; see also **Sections 10.04.3, 10.04.4**, and **10.04.5**). However, the quality factor Q of the planets is not well known, nor is its frequency (or rotation rate) dependence well understood (see, e.g., Anderson, 1989; Lambeck, 1980; Munk and MacDonald, 1960). Often, it is assumed that Q is constant for large frequencies (for fast rotation, the main tidal frequency $\sigma \approx 2\omega$) as in seismology (e.g., Dahlen and Tromp, 1998) and inversely proportional to frequency for small frequencies (the main tidal frequency can be small for $\omega \sim n$). The latter case corresponds to a constant phase lag Δt, and dissipation then vanishes when the tidal frequency goes to zero. Zero tidal frequency implies that the tidal bulge is static with respect to the planet, and $\delta = 0$. During the rotation history of a planet, the torque and the despinning rate can change through the frequency dependence of Q and as a result of internal planetary changes that can affect C and k_2.

For slowly rotating planets, the sign of the effect of the solar tidal torque on the rotation rate depends on the obliquity, with two regions separated by an equilibrium point for the rotation rate given by

$$\omega_e = \left(\frac{2\cos\varepsilon}{1+\cos^2\varepsilon}\right)n + \mathcal{O}(e^2) \qquad [59]$$

when dissipation is assumed to be linear with frequency (or the time lag constant) (Correia and Laskar, 2003a). When $\omega > \omega_e$, the rotation rate of the planet decreases, whereas it increases for $\omega < \omega_e$. For an initially rapidly rotating planet, the rotation rate tends to decelerate to this equilibrium rotation rate.

Besides changing the rotation rate of a planet, the tidal torque also changes the obliquity as the tidal bulge is carried outside the orbital plane by rotation during the time lag for obliquities different from 0° and 180°. When the time lag is assumed to be constant and the eccentricity is negligibly small, $\varepsilon = 0°$ and $\varepsilon = 180°$ are unstable equilibrium points and $\varepsilon = \arccos(2n/\omega) = \varepsilon_0$ is a stable equilibrium for fast rotation ($\omega > 2n$) (Goldreich and Peale, 1970; Néron de Surgy and Laskar, 1997). Obliquity increases when $\varepsilon < \varepsilon_0$ and decreases otherwise. The stable equilibrium is between 0° and 90° for prograde rotation and tends to zero obliquity for a decreasing rotation rate. Tidal torques can therefore not overturn an initially prograde planet to a retrograde rotation. For slow rotation ($0 < \omega < 2n$), $\varepsilon = 0°$ is a stable equilibrium point and $\varepsilon = 180°$ an unstable point. Because tidal friction tends to drive the rotation rate ω to the slow rotation regime (eqn [59]), obliquity is eventually driven to 0°, and the rotation rate tends to the mean motion (1:1 resonance). For a non-circular orbit, the final tidally evolved state is commensurate but not synchronous with the mean orbital motion. This will be discussed further in **Section 10.04.5** on Mercury.

10.04.2.4.2 Thermal atmospheric tides

A conceptually related dissipation effect on planetary rotation is due to thermal tides in the atmosphere, first shown by Lord Kelvin (Thompson, 1882). The Sun heats the atmosphere and the surface most at the subsolar point and causes pressure changes and mass motion, or thermal tides, in the atmosphere from the subsolar point to the less heated zones. The main thermal tides of the Earth are semidiurnal and the atmospheric 'bulge' is almost perpendicular to the Earth–Sun direction (Chapman and Lindzen, 1970). When one takes into account a not too large response times, it follows that the solar torque on the bulge, for rapidly rotating planets ($\omega > 2n$), has an effect on the rotation rate of the planet opposite to that of the solar torque on the gravitational tidal bulge: it accelerates the rotation rate (e.g., Dobrovolskis and Ingersoll, 1980; Gold and Soter, 1969; Munk and MacDonald, 1960). Because the torque acts on the atmospheric bulge, it is assumed here that the resulting change in angular momentum of the atmosphere is transmitted to the solid body to maintain a rotation of the atmosphere not too dissimilar from that of the solid body.

The pressure perturbation in the atmosphere is inversely proportional to the tidal frequency (Chapman and Lindzen, 1970). Therefore, the effect of thermal tides on the rotation can be neglected for fast rotation ($\omega \gg n$), and a deceleration from an initial fast rotation to a rotation commensurate with the orbital rotation is dominated by the gravitational solid-body tides. Evidently, torques on the atmospheric thermal tides are mainly important for planets with a dense atmosphere, and dissipation models have mainly been developed for the Earth and Venus (e.g., Chapman and Lindzen, 1970; Dobrovolskis and Ingersoll, 1980).

For $\omega > 2n$, the thermal tides tend to bring the obliquity to either one of the two stable equilibrium points, at $\varepsilon = 0°$ and at $\varepsilon = 180°$ for zero eccentricity, depending on the obliquity being smaller or larger than an unstable equilibrium obliquity value. This critical obliquity depends on w and goes to zero for $\omega \gg n$ and to 180° for $\omega \to 2n$ (Correia and Laskar, 2003a). For initial obliquities larger than the critical obliquity but smaller than 90°, thermal tides can therefore tend to increase the obliquity and tend to overturn a planet that initially rotates rapidly in the prograde sense (Dobrovolskis, 1980; Lago and Cazenave, 1979; Yoder, 1995).

10.04.2.4.3 Core–mantle friction

Friction torques associated with differential rotation between a liquid core and a solid mantle can also change the rotation of a planet on long timescales. In our analysis of periodic rotation variations, the friction torques were neglected in a lowest-order approximation as their effects are expected to be small on short timescales. Nevertheless, friction torques have an observable effect on the nutations of the Earth (e.g., Buffett, 1992; Buffett and Christensen, 2007; Buffett et al., 2002; Deleplace and Cardin, 2006; Dumberry and Koot, 2012; Mathews and Guo, 2005; Mathews et al., 2002). For secular changes in the rotation, even small dissipation effects can eventually have important effects. Two different friction torques must be considered: the viscous torque due to viscosity of the core liquid and the electromagnetic torque between the core and the mantle resulting from the electric currents in the conducting bottom mantle layer (see also **Section 10.04.5.3**). Both torques are linearly proportional to the difference of the rotation vectors of the mantle and core (e.g., Rochester, 1976). For the electromagnetic torque, this can be understood by noting that the magnetic field involved in the coupling is induced by the relative velocity between the mantle and the core. Therefore, usually a single friction torque is considered with parameters that include the effects of both the viscous coupling and the electromagnetic coupling.

In response to precession, an additional flow of uniform vorticity is set up in the core (Hough, 1895, Poincaré, 1910). Without core viscosity, the vorticity of this flow is in the direction of $\vec{\omega} \times \left(\vec{\Omega}_P \times \vec{\omega}\right)$, where $\vec{\Omega}_P$ is the angular velocity of precession oriented normal to the orbital plane (e.g., Stewartson and Roberts, 1963). The vorticity is thus in the $\left(\vec{\omega}, \vec{\Omega}_P\right)$-plane, and the core rotation vector is coplanar with $\vec{\omega}$ and $\vec{\Omega}_P$. Since the additional flow is steady in a precessing frame (the core coprecesses with the mantle), the change in the additional core angular momentum is in the direction of $\vec{\Omega}_P \times \left[\vec{\omega} \times \left(\vec{\Omega}_P \times \vec{\omega}\right)\right]$ (Pais et al., 1999). By using the conservation of angular momentum, it follows that the change in the angular momentum $I\vec{\omega} \approx C\vec{\omega}$ along the rotation axis of the mantle is in the opposite direction. Because that vector is perpendicular to $\vec{\omega}$ and $\vec{\Omega}_P$, there is no corresponding change in $H = C\omega$ nor in $X = C\omega\cos\varepsilon$, so neither the obliquity nor the rotation rate changes.

Core viscosity tends to decrease the relative velocity between the mantle and the core and to make the core precession to lag behind the mantle precession. The additional flow vorticity thus has a component in the direction perpendicular to $\left(\vec{\omega}, \vec{\Omega}_{\mathrm{P}}\right)$ (Busse, 1968; Roberts and Stewartson, 1965; Rochester, 1976; Stewartson and Roberts, 1963), and the change in angular momentum $C\vec{\omega}$ has an additional component in the direction of $\vec{\Omega}_{\mathrm{P}} \times \left(\vec{\omega} \times \vec{\Omega}_{\mathrm{P}}\right)$, which is perpendicular to $\vec{\Omega}_{\mathrm{P}}$ but not to $\vec{\omega}$. As a result, H changes in time and $X = H\cos\varepsilon$ remains constant. When the rotation rate changes because of core–mantle friction, the obliquity ε must also change to keep the component of the spin angular momentum normal to the orbital plane constant:

$$\frac{\mathrm{d}\varepsilon}{\mathrm{d}t} = \cot\varepsilon \frac{1}{\omega}\frac{\mathrm{d}\omega}{\mathrm{d}t} \qquad [60]$$

Since the dissipated energy must come from the rotation, core–mantle friction torques cause the rotation to slow down and the obliquity to evolve to either 0° or 180°, depending on the initial obliquity being smaller or larger than 90° (Correia and Laskar, 2003a; Goldreich and Peale, 1970; Néron de Surgy and Laskar, 1997; Pais et al., 1999; Rochester, 1976; Yoder, 1995).

A main problem of core–mantle friction models is that the viscosity of the cores of terrestrial planets is poorly known (Anderson, 1989). Moreover, a turbulent boundary layer close to the CMB can develop (e.g., Yoder, 1995). Core–mantle friction becomes more important for increasing core differential rotation with respect to mantle during precession, and at the same time, turbulence is more likely then. If the FCN period is much smaller than the precession period (such as for rapidly rotating planets as the Earth and Mars at present), the core efficiently tracks the precession of the mantle, and the effect of core–mantle friction on the long-term changes of the rotation of the planet is weak (for the effect on the Earth, see, e.g., Néron de Surgy and Laskar, 1997; Pais et al., 1999). For slowly rotating planets,

$$\frac{P_{\mathrm{FCN}}}{P_{\mathrm{Pression}}} \propto \left(\frac{n}{\omega}\right)^2 \qquad [61]$$

(see eqns [5] and [48]), and the differential rotation between the core and the mantle can become larger. Therefore, core–mantle friction can become the dominant cause of secular rotation variations if rotation is slow enough.

10.04.2.4.4 Climate friction

It is well known that obliquity variations induce climate changes. However, the climate can also change the obliquity of a planet by altering the mass distribution in the planet (Rubincam, 1990). In particular, during glacial cycles, mass is transported between the fluid layers (atmosphere and oceans) and the polar caps. This changing surface load also induces a partially compensating internal mass redistribution. Together, they lead to polar motion and small variations in the rotation rate on the timescale of the glacial cycles (Munk and MacDonald, 1960). Climate cycles also act to modify the polar flattening of the planet, and therefore, the precession rate will vary. For the Earth, the oblateness can change by as much as 1% (Thomson, 1990).

Due to the fact that the mantle is viscous, the changes in the equatorial bulge will lag behind the obliquity changes and will result in a long-term effect on the obliquity. This mechanism was first described by Rubincam (1990) and called 'climate friction.' Despite many unknowns in the climate and viscous response to obliquity oscillations, most recent analyses suggest that the climate friction effect on the long-term obliquity variations of the Earth and Mars is small compared to the planetary effect on obliquity, with obliquity changes below 1° during the age of the solar system for Mars and Earth obliquity changes smaller than 0.01° per My during the major recent Pliocene–Pleistocene glaciations (Levrard and Laskar, 2003; Spada and Alfonsi, 1998 but see also Williams et al., 1998).

10.04.3 Mars

10.04.3.1 Current Rotation State

Christiaan Huygens was the first to observe that the rotation period of Mars is similar to that of the Earth. On 1 December 1659, he noted (in Latin) in his journal that "the rotation period of Mars, like that of the Earth, seems to be in a period of twenty-four hours" (see Kieffer et al., 1992). The period was confirmed in 1666 by Giovanni Domenico Cassini, who determined a value of 24 h and 40 min. Herschel (1774) estimated the obliquity of Mars to be about 30°. The rotation period determined from Doppler and range measurements to the Mars Pathfinder lander and the Viking landers is 88642.66302 ± 0.00002 s, or 24 h 37 min 22.66302 ± 0.00002 s, and the obliquity $\varepsilon = 25.189417 \pm 0.000033°$ (Folkner et al., 1997a). The inclusion of Doppler and range tracking data from the orbital missions Mars Global Surveyor (MGS), Odyssey, and Mars Reconnaissance Orbiter (MRO) slightly improved the estimates of the rotation period 24 h 37 min 22.662993 ± 0.000003 s and obliquity $\varepsilon = 25.1893792424 \pm 0.000010°$ (Konopliv et al., 2011). The spin period here is relative to the node of the Mars mean orbit and Mars mean equator of date.

10.04.3.2 Long-Term Spin Evolution

Because Mars is far from the Sun and has no large moons, tidal braking has only had a small influence on its rotation (Goldreich and Soter, 1966). As the effects of thermal tides in the tenuous Martian atmosphere and of core–mantle friction for a rapidly rotating planet are even smaller (see **Section 10.04.2.4**), the rotation speed of Mars can be considered to be primordial (Laskar et al., 2004). The dissipative effects on obliquity variations are equally small, and planetary perturbations on the orbital motion of Mars dominate the changes in obliquity. The obliquity variations depend sensitively on the precession rate (see **Section 10.04.2.3**), which is well known with a precision below 1%:

$$\dot{\psi} = (-7594 \pm 10) \times 10^{-3} \text{arcsec year}^{-1} \qquad [62]$$

(Konopliv et al., 2011). This estimate has been determined from the Doppler and range data to the Mars Pathfinder lander and the Viking landers and from radio-tracking data of MGS,

Odyssey, and MRO and is close to the value determined on the basis of lander data only (Folkner et al., 1997a).

Because the current precession frequency of Mars is close to some major secular frequencies of the orbital precession, Mars' obliquity performs large chaotic variations (Laskar and Robutel, 1993; Touma and Wisdom, 1993; Ward, 1974). Therefore, the evolution of obliquity cannot be determined over long timescales, and the present obliquity cannot be considered as being primordial. In a statistical study of the orbital and rotational evolution of Mars, Laskar et al. (2004) demonstrated that the current accurately determined precession rate allows constructing reliable obliquity evolutions over 10–20 My. Sufficiently accurate initial conditions such as the current precession rate are needed because the motion of Mars' spin axis is chaotic. These authors also calculated the mean and most probable obliquity values over 4 Gyr: Mars seems to have a much lower obliquity now than its mean value of about 37.62° and its most probable value of about 41.80°. Obliquity and precession are important constraints on the solar insolation and hence on the climate history and the evolution of the polar caps of Mars. In particular, the present 'low' obliquity suggests that the present climate is not representative. We refer to Laskar et al. (2004) and references therein for an extensive study of the astronomical forcing of the Martian paleoclimate.

By using eqn [5], and correcting for the relativistic geodetic precession of 6.7 mas year^{-1} (Reasenberg and King, 1979) and for the precession of -0.2 mas year^{-1} caused by the other planets, the polar moment of inertia C of Mars can be derived from the precession rate as $C=(0.3664\pm0.0005)\ MR^2$ (Konopliv et al., 2011). All other quantities in eqn [5] for the precession rate, including the coefficient J_2 of the gravitational field, are well known. The moment of inertia measures the radial mass concentration and is an important and the best determined constraint on the interior structure of Mars (see **Chapter 10.02**).

10.04.3.3 Nutation

The observation of nutations of Mars can provide insight into the interior of Mars. If Mars were to behave rigidly, nutations would only give a constraint on the moment of inertia, in addition to the constraint from precession. However, the nonrigid behavior contains important geophysical information, in particular on the core. Because the nonrigid contributions to the nutation amplitudes are currently below the limit of detectability, theoretical nutation models are used, and needed, in the analyses of radio science data (Konopliv et al., 2006; Yoder and Standish, 1997). Improved radio science experiments could allow distinguishing the nonrigid contributions and so offer a direct way to study properties of the deep interior of Mars. A small network of a few fixed landers with dual-band coherent radio transponders would be particularly suited. In 2016, NASA will launch a single geophysical lander, InSight, which will enable measuring Mars' nutations. In this section, we review the current theoretical knowledge on the nutation of Mars and discuss the geophysical potential of nutation observations.

10.04.3.3.1 Rigid nutations

The celestial mechanical problem of determining the tidal potential is most conveniently separated from the geophysical problem of calculating the rotational response to forcing by first deriving the nutations under the assumption that Mars responds as a rigid body to the gravitational (tidal) torques. Rigid nutation series for the angular momentum axis can be easily derived from eqn [1] by explicitly expressing the three components in terms of an inertial reference frame. After rewriting the torque components in terms of another nonrotating reference frame with first axis toward the ascending node of Mars' orbital plane on Mars' equator of date and the third axis in the direction of the angular momentum axis, and approximating the magnitude of the angular momentum vector by $C\Omega$ since the equatorial components of the angular momentum are very small compared to the polar component, we obtain

$$\frac{\mathrm{d}\Delta\psi}{\mathrm{d}t}=\frac{1}{C\Omega}\frac{L_1}{\sin\varepsilon} \qquad [63]$$

$$\frac{\mathrm{d}\Delta\varepsilon}{\mathrm{d}t}=\frac{1}{C\Omega}L_2 \qquad [64]$$

where $\Delta\psi$ and $\Delta\varepsilon$ are the periodic nutations in longitude and obliquity and (L_1, L_2) are the equatorial components of the torque with the first component in the direction of the ascending node of Mars' orbital plane on Mars' equator of date (Moritz and Mueller, 1987; Roosbeek, 1999). Equivalent expressions in a Hamiltonian theory are given in Bouquillon and Souchay (1999). For each interacting body of the solar system sufficiently far from Mars such that the torque can be approximated by its degree-two terms, we have

$$\frac{\mathrm{d}\Delta\psi}{\mathrm{d}t}=\frac{1}{\Omega}\frac{1}{\sin\varepsilon}\frac{GM}{r^3}\frac{\left(C-\overline{A}\right)}{C}\frac{3}{2}\sin2\delta\sin\alpha \qquad [65]$$

$$\frac{\mathrm{d}\Delta\varepsilon}{\mathrm{d}t}=-\frac{1}{\Omega}\frac{GM}{r^3}\frac{\left(C-\overline{A}\right)}{C}\frac{3}{2}\sin2\delta\cos\alpha \qquad [66]$$

where M is the mass of the perturbing body, r the distance to the perturbing body, and δ and α the declination and right ascension of the perturbing body, respectively. Triaxial effects of Mars are neglected here and $\overline{A}=(A+B)/2$. The equatorial torque components and the nutations can then be calculated from the ephemerides of the planets and moons (e.g., Borderies, 1980; Hilton, 1991; Reasenberg and King, 1979). The most recent and accurate nutation series (Bouquillon and Souchay, 1999; Roosbeek, 1999) are accurate up to 0.1 mas and are based on the VSOP87 ephemerides for the planets (Bretagnon and Francou, 1988), which are valid for a few 1000 years around J2000.0 and include orbit perturbations due to the other planets. For Phobos and Deimos, the ESAPHO and ESADE ephemerides were used (Chapront-Touzé, 1990).

At a given tidal frequency σ_j', nutation can be expressed either as a sum of a sine and a cosine term in both longitude and obliquity or as a sum of two circular nutations, one prograde and the other retrograde (as compared to the rotation of the planet):

$$\begin{aligned}\Delta\varepsilon+\mathrm{i}\sin\varepsilon_0\Delta\psi&=\sum_j\left[A_j\mathrm{e}^{\mathrm{i}\left(\sigma_j't+f_j\right)}-A_{-j}\mathrm{e}^{-\mathrm{i}\left(\sigma_j't+f_j\right)}\right]\\&=\sum_j\left[\left(A_j-A_{-j}\right)\cos\left(\sigma_j't+f_j\right)+\mathrm{i}\left(A_j+A_{-j}\right)\sin\left(\sigma_j't+f_j\right)\right],\end{aligned} \qquad [67]$$

where ε_0 is the obliquity at J2000.0 (see, e.g., Defraigne et al., 1995).

The largest nutation of Mars considered as a rigid body is the prograde semiannual nutation with an amplitude of about 500 mas (Bouquillon and Souchay, 1999; Roosbeek, 1999). Semiannual here refers to a period of half a Martian year. For the ideal case of a single biaxial planet in circular orbit about the Sun, the semiannual nutation would be the only nutation. In that case, the torque on the planet is equal and maximal at summer and winter solstices. Other nutations are due to deviations with respect to this ideal case. The amplitude of the semiannual nutation is almost equal to that of the Earth. Three factors in the nutation amplitude contribute to this near equality. First, the torque depends on the third power of the distance of the planet to the Sun, which is about 1.5 times larger for Mars than for the Earth. Secondly, the nutation amplitude is proportional to the period (see eqn [19]), which is about 1.88 times longer for Mars than for the Earth. These two factors can be combined by Kepler's third law into a nutation amplitude inversely proportional to the period. Thirdly, the dynamic flattening $H_D=(C-\overline{A})/C$ of Mars is about 5/3 of the flattening of the Earth.

The amplitudes of the four main retrograde nutations are about 137, 18, 5, and 1 mas for periods of 1, 1/2, 1/3, and 1/4 year, respectively (Roosbeek, 1999; values have been rescaled to use the most recent precession estimate of Konopliv et al., 2011). The prograde nutations at 1, 1/2, 1/3, and 1/4 year have amplitudes of 102, 499, 108, and 18 mas. All these nutations are due to the gravitational torque of the Sun. The nutations due to Mars' moons have amplitudes of about 10 mas for Phobos and 5 mas for Deimos and periods of 2.26 years and 54.754 years, respectively (Bouquillon and Souchay, 1999; Roosbeek, 1999). The largest nutations caused by the direct gravitational torque from planets are on the order of 0.1 mas and are due to Jupiter and the Earth.

Differences between the nutations for the angular momentum, the rotation axis, and the figure axis are at most on the order of 0.1 mas and can be neglected (Bouquillon and Souchay, 1999; Roosbeek, 1999). The largest uncertainty on the rigid nutation amplitudes is due to the observational error on the precession rate. Both precession and nutation depend linearly on the dynamic flattening $H_D=(C-\overline{A})/C$ (Roosbeek, 1999). Any relative error on the precession rate translates into the same relative error on H_D and on the nutations. With the newest and most accurate precession rate of Konopliv et al. (2011), the value used in the nutation amplitudes mentioned earlier, the relative uncertainty of 0.13% on the precession rate implies an uncertainty on the main nutation of 0.6 mas.

10.04.3.3.2 Nonrigid nutations

A nonrigid nutation series is derived from a rigid nutation series by means of a transfer function $T(\sigma)$, which describes the ratio of the nonrigid nutation amplitude to the rigid nutation amplitude for frequency σ (Dehant et al., 2000a). We will use a transfer function for a planet with a liquid core because Mars most likely has a – at least partially – liquid core as indicated by the fact that the Love number $k_2=0.164\pm0.009$ (Konopliv et al., 2011) is clearly larger than the value of about 0.07 for an entirely solid Mars (Rivoldini et al., 2011; Van Hoolst et al., 2003; Yoder and Standish, 1997). Thermal evolution models also point to an at least partially liquid core (Schubert and Spohn, 1990; Stevenson et al., 1983). For a planet with a solid mantle and a liquid core, the transfer function can be derived from Liouville equations [23]–[25] and [32]–[34] as

$$T(\sigma)=\frac{(\sigma-\sigma_E)\left(A\sigma'-A^m\sigma'_{FCN}\right)}{A^m(\sigma-\sigma_{CW})(\sigma-\sigma_{FCN})} \qquad [68]$$

which shows that nutations are resonant at frequencies equal to the CW frequency and the FCN frequency. For a planet containing also a solid inner core, resonances with the FICN and the ICW must additionally be considered. The FCN is particularly important because it has a long retrograde period in an inertial reference frame between about 200 and 300 days, depending on the interior structure, close to the periods of the main nutations (see eqn [48], Hilton, 1992; Van Hoolst et al., 2000b; Yoder and Standish, 1997). Therefore, the FCN can have a large effect on nutation and the amplifications, and amplitudes, of the retrograde nutations depend sensitively on the model (Dehant et al., 2000a,b; Le Maistre et al., 2012; Molodensky et al., 2009; see **Figure 2**). For the Earth, relatively large resonant nutation amplifications have been detected and have been used to demonstrate that the flattening of the core is larger than that of a hydrostatic Earth based on the PREM model (Gwinn et al., 1986; Mathews et al., 1991, 2002).

The amplification of the largest nutation with prograde semiannual period depends much less on the FCN period since it is much further from the retrograde FCN period and thus from the resonance peak. Nevertheless, as it is the largest nutation, its amplification with respect to the rigid nutation term is still about 5 mas, for any realistic model of Mars' interior. Future determinations of the amplitudes of nutation terms with a radio science experiment are expected to have a precision on the order of a mas (Dehant et al., 2000a;

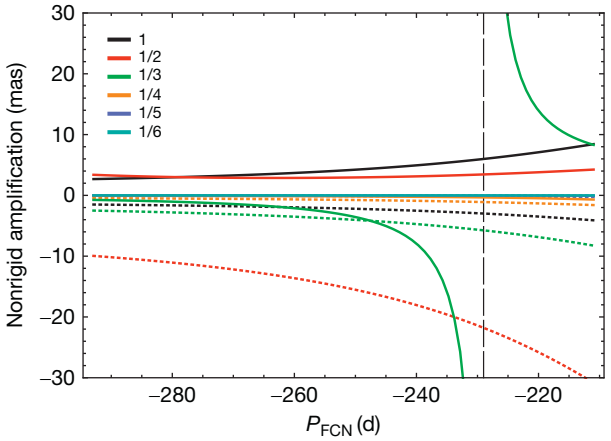

Figure 2 Amplification of prograde (dashed lines) and retrograde (solid lines) nutations with respect to rigid nutation amplitudes for the nutations with periods equal to 1 Martian year (1), half a Martian year (1/2), and up to one-sixth of a Martian year (1/6) as a function of the FCN period for a selected set of basic two-layer models of the interior structure of Mars satisfying the observed mass and moment of inertia.

Le Maistre et al., 2012). Only for the prograde semiannual nutation is the amplification always above the observational precision and larger than the uncertainty on the rigid amplitude, irrespective of the interior structure of Mars. Therefore, this nutation is ideally suited for further independent evidence of the liquidity of the core.

Besides establishing the liquidity of the Martian core, the nutations can be used to constrain other properties of the interior of Mars, by making use of the resonances of the main nutations with rotational normal modes whose frequencies depend sensitively on Mars' interior. The FCN period depends mainly on the CMB polar flattening α^f because the restoring force for this normal mode is proportional to that flattening and on the moment of inertia of the core. It therefore decreases in absolute values with increasing core radius and is a good indicator of core density (Van Hoolst et al., 2000a). Because the FCN eigenfunction represents essentially rotational motion, the influence of uncertainties on rigidity, incompressibility, and mantle inelasticity on the FCN period is small (Hilton, 1992; Le Maistre et al., 2012; Molodensky et al., 2009; Van Hoolst et al., 2000a,b). For realistic models of Mars' interior in hydrostatic equilibrium with an inner core radius of about 1800 km, a mean value derived from the observed k_2 Love number (Rivoldini et al., 2011), the retrograde FCN period is expected to be between about 220 and 280 days (Le Maistre et al., 2012) so that a resonant amplification of the terannual retrograde nutation is possible.

The closer the FCN period is to one of Mars' main nutations, the more accurately the FCN period and thus the core radius and density of Mars can be determined. After 50 weeks of Doppler tracking observations, with a precision of 1 mm s^{-1}, between four landers and an orbiter, and the orbiter and the Earth, the FCN period is expected to be determined with a 10-day uncertainty (Yseboodt et al., 2003) for an FCN well separated from the terannual period. For one nearly equatorial lander, the FCN period is estimated with a similar precision after 550 days of mission (Le Maistre et al., 2012). For an FCN period equal to −230 days, close to the terannual period of 228.9 days, a precision of 1 day is reached after 300 days of observations. After 1 year, a precision of 30% on the core moment of inertia and of 5% on the CMB flattening can be obtained (Le Maistre et al., 2012).

Mantle convection and the presence of a solid inner core could complicate the interpretation of the nutation amplitudes. Mantle convection can deform the CMB and change the core flattening. In particular, the Tharsis region, which is the dominant topography on Mars, is partially associated with a hot upwelling plume in the mantle (Harder and Christensen, 1996; Kiefer et al., 1996; Roberts and Zhong, 2004). As Tharsis is situated in an equatorial area, it increases the polar flattening of the core. Steady state convection models that account for the geoid high at Tharsis show that the FCN frequency can be decreased down to about 100 days, in particular when no lower mantle perovskite layer is present (Defraigne et al., 2001). The FCN resonance then shifts to smaller rigid nutation terms (see **Figure 2**). Yoder et al. (2003) showed that at least the outer part of the core is liquid, but it is not known with certainty whether there would be a solid inner core, nor how large it would be. The main uncertainties are the temperature profile and the concentration of light elements in the core, especially sulfur, which has a large effect on the melting temperature of the core assemblage (Schubert and Spohn, 1990; Spohn, 1991). Using SNC meteorites, Dreibus and Wänke (1985) showed that the percentage of sulfur in the core is about 14 wt.%. Such a high sulfur content tends to keep the core entirely liquid (Breuer and Spohn, 2003; Schubert and Spohn, 1990; Schubert et al., 1992). In a recent analysis of the observed k_2 Love numbers, this large sulfur content was confirmed, under the condition that sulfur is the only light element in the Martian core, and the core was concluded to be entirely liquid for realistic temperature profiles (Rivoldini et al., 2011).

The absence of a magnetic field of a global scale has also been used to argue against the existence of a solid inner core (e.g., Breuer and Spohn, 2003) since a growing inner core is very efficient in driving a dynamo. Nevertheless, core growth could be too small to sustain a dynamo, might be in a regime where the solidifying material has the same composition as the liquid, or could have stopped due to core reheating after an early period of global plate tectonics (Stevenson, 2001). Besides dynamo studies and thermal evolution calculations, observations are needed to decide upon the existence of an inner core. Nutation observations could help in deciding about the existence and size of the Martian inner core. When the outer core has a sulfur concentration below the eutectic value, the inner core influence on the nutations is below 1 mas except if the FICN period happens to be very close to the prograde annual or semiannual nutation (Defraigne et al., 2003; Dehant et al., 2003; Van Hoolst et al., 2000b). The observation of such an amplification would be a strong indication for the existence of an inner core but would require a lucky coincidence. For progressively larger inner core, the amplification due to the FCN resonance of the largest nutation, the prograde semiannual, is almost canceled by the resonance with the FICN, whose period decreases rapidly to zero in the limit of an entirely solid core (Defraigne et al., 2003). Failure to detect amplification of the semiannual nutation with a future sufficiently accurate geodesy experiment could then be interpreted as evidence for a large inner core.

10.04.3.4 Rotation Speed Variations

The atmosphere of Mars consists of 95% carbon dioxide (CO_2) (Owen et al., 1977), which condenses during the winter seasons at high latitudes to form periodic polar CO_2 caps. During spring and summer seasons, the caps sublime and the mass is again redistributed in the atmosphere (James et al., 1992). In this seasonal cycle of mass transfer between the atmosphere and the polar caps, a large fraction of the total mass of the atmosphere condenses at the polar regions. The maximum mass of the north and south seasonal caps is $3.0 \pm 1.0 \times 10^{15}$ kg and $5.5 \pm 1.0 \times 10^{15}$ kg, respectively (Karatekin et al., 2006b; Konopliv et al., 2006; Litvak et al., 2006; Prettyman et al., 2009), or about one-quarter of the total mass of the atmosphere of about 2.5×10^{16} kg (Lodders and Fegley, 1998). Because of the conservation of angular momentum, this large mass redistribution by seasonal sublimation and condensation of CO_2 and the (associated) winds can

induce seasonal changes in the rotation of Mars. The more the mass is concentrated in the polar regions, as solid CO_2 ice in the polar caps, the smaller the moment of inertia C about the polar axis is and the faster Mars rotates. When the polar caps sublime, the CO_2 is distributed more uniformly over the Martian surface and Mars rotates slower. Qualitatively, the effect on rotation scales as the ratio of the net redistributed mass to the planet's total mass (Chao and Rubincam, 1990). This ratio is about 1.3×10^{-8}, at least one to two orders of magnitude larger than any mass redistribution on Earth, suggesting large rotation rate variations.

The redistribution of matter is mainly in the north/south direction. If the growth of one polar cap would be symmetrical with respect to the retreat of the other polar cap, there would be no net change in the moment of inertia of Mars, and only winds in the atmosphere could change the rotation rate. In reality, the caps do not grow symmetrically. Since the orbit of Mars is quite eccentric (eccentricity equal to 0.0934), the temperatures at the two poles differ for a given season, and the seasons do not have the same length on both hemispheres. For example, winter on the southern hemisphere lasts almost a month longer than on the northern hemisphere (Kieffer et al., 1992). Differences in polar topography, thermal inertia, and albedo further contribute to asymmetry between the increase and the decrease of the two polar caps.

Seasonal changes in the rotation speed of Mars have first been detected from radio-tracking data to the Viking landers (Folkner et al., 1997a; Reasenberg et al., 1980; Yoder and Standish, 1997). Although the rotation rate variations can best be determined from a lander, more recent solutions are based on MGS, Odyssey, and MRO tracking data, which are both qualitatively and quantitatively better than the older Viking data. Solutions based on the orbiter tracking data are consistent with the lander data within the uncertainties (Konopliv et al., 2006). Using both lander and orbiter data, Konopliv et al. (2011) determined amplitudes of 456 ± 23 mas, 154 ± 21 mas, 24 ± 19 mas, and 10 ± 16 mas for the rotation angle variations at 1-, 1/2-, 1/3-, and 1/4-year period, respectively. In these studies, a theoretical nutation model is included. If it were omitted, it would substantially change the estimates of the seasonal rotation variations (see, e.g., Yoder et al., 2003).

Instead of rotation angle variations, relative changes in the rotation rate $\delta\omega_3/\Omega = m_3$, changes in the length of the day, $\mathrm{LOD}(t) = 2\pi/\omega_3(t)$, or variations in the time needed for the planet to rotate over the angle $\phi(t)$ at constant angular velocity Ω are often used to describe rotation variations. The latter variations are denoted as δUT by analogy with LOD variations for the Earth. We have the following useful relations between the rotation variations:

$$\frac{\Delta\mathrm{LOD}(t)}{\mathrm{LOD}} = -m_3(t), \qquad [69]$$

$$\delta\phi(t) = \Omega \int_{t_0}^{t} m_3(t')\mathrm{d}t' \qquad [70]$$

$$\delta\mathrm{UT}(t) = \int_{t_0}^{t} m_3(t')\mathrm{d}t' \qquad [71]$$

$$= \frac{1}{\Omega}\delta\phi(t) \qquad [72]$$

$$= -\frac{\Omega}{2\pi}\int_{t_0}^{t} \Delta\mathrm{LOD}(t')\mathrm{d}t' \qquad [73]$$

For a periodic variation with frequency ω, the amplitudes A_{LOD}, A_{UT}, A_{m_3}, and A_ϕ of the variations in LOD, UT, m_3, and ϕ, respectively, are related by

$$A_{m_3} = \omega A_{\mathrm{UT}} = \frac{\Omega}{2\pi} A_{\mathrm{LOD}} = \frac{\omega}{\Omega} A_\phi \qquad [74]$$

As an example, the observed amplitude $A_\phi = 456$ mas of the annual rotation variations (Konopliv et al., 2006) corresponds to amplitudes $A_{\mathrm{UT}} = 31.9$ ms, $A_{m_3} = 3.37 \times 10^{-9}$, and $A_{\mathrm{LOD}} = 0.299$ ms. For the semiannual amplitude, we have $A_\phi = 154$ mas, $A_{\mathrm{UT}} = 10.6$ ms, $A_{m_3} = 2.23 \times 10^{-9}$, and $A_{\mathrm{LOD}} = 0.198$ ms. Hereafter, only rotation variations in mas will be quoted.

With modern radio tracking of a lander over at least one Martian year, the accuracies on the rotation variations could be increased. Because the older Viking data are an order of magnitude less precise than modern X-band tracking data and the rotation estimates based on them and on Mars Pathfinder data are of comparable accuracy to those based on the modern spacecraft data, an order of magnitude improvement can be expected. Direct two-way range and X-band Doppler measurements between an Earth tracking station and a lander on Mars, or Earth-based radio-tracking observations of an orbiter that is itself tracking one or more landers, would enable the determination of the rotation variations with an accuracy of a few mas (Barriot et al., 2001; Dehant et al., 2009, 2011; Folkner et al., 1997b; Le Maistre et al, 2012; Yseboodt et al., 2003).

Theoretical estimates of rotation rate variations were first derived by Philip (1979), who used Viking data to calculate the atmospheric friction torque associated with zonal winds. This torque transfers angular momentum between the atmosphere and the solid planet and causes rotation rate variations. Although the torque approach gives insight into the mechanisms transferring angular momentum between the solid body and the atmosphere, most studies have used an angular moment approach as developed in **Section 10.04.2** since this has proven to be more reliable (see also Sanchez et al., 2003). Wind and loading data to calculate the excitation functions or the angular momentum functions of **Section 10.04.2** can be obtained from general circulation models (GCMs) of the Martian atmosphere or from physical considerations on mass redistribution within the Martian atmosphere and polar caps (see, e.g., Chao and Rubincam, 1990; Yoder and Standish, 1997). Recent GCMs were used by Van den Acker et al. (2002) and Sanchez et al. (2003). The former study used the Martian Climate Database v3 from the Laboratoire de Météorologie Dynamique (LMD) in Paris, France (Forget et al., 1999; Lewis et al., 1999), while the latter the NASA Ames GCM (Pollack et al., 1990).

The estimated annual and semiannual rotation angle amplitudes are 394 and 192 mas, respectively, in the study of Van den Acker et al. (2002) and correspond reasonably well with the observational values of Konopliv et al. (2006) within their uncertainties. The annual and semiannual amplitudes of

Sanchez et al. (2003) are 291 and 106 mas, respectively. The latter study did not include effects of elastic deformation and of a liquid core. The loading effect of Van den Acker et al. (2002) is in better agreement with the theoretical estimates of Yoder and Standish (1997), who not only used a simpler model for the atmospheric and ice cap loading (see also Chao and Rubincam, 1990) but also included effects of elastic yielding and a liquid core, suggesting that these effects could explain the difference with Sanchez et al. (2003). The deformational effect decreases the rotation variations by about 8% (Defraigne et al., 2000). As the ratio C/C^{m} is only about 1.03 (the value for the standard model A of Sohl and Spohn, 1997; see, e.g., Van Hoolst et al., 2000b), a liquid core increases LOD variations at most by about 3%. However, this effect is to a large extent compensated by the different deformational effect (k_2' in eqn [45]). Deformation tends to decrease rotation variations, and its effect on rotation is a few percent larger for a liquid core than for a solid core. As a result, the effect of the state of the core is very small and on the order of 1% (Defraigne et al., 2000; Karatekin et al., 2006a). The differences between the results of Van den Acker et al. (2002) and Sanchez et al. (2003) can therefore not be explained in terms of the neglect of these effects by Sanchez et al. (2003), but are most likely due to differences in the atmospheric models. This indicates that ΔLOD observations are useful to constrain the GCMs. Note that rotation differences between GCM models having different atmospheric dust contents and dust storms with respect to the standard model for the 'mean' climate of Mars are about one order of magnitude larger than the expected accuracy of future ΔLOD measurements (Defraigne et al., 2000; Van den Acker et al., 2002).

The separate effects of wind, atmospheric loading, and ice cap loading can be studied with the angular momentum approach. The winds have the smallest effect on the rotation rate of Mars in contrast with the Earth where the winds are the dominant source for seasonal LOD variations (Cazenave and Balmino, 1981; Defraigne et al., 2000; Gross et al., 2004; Van den Acker et al., 2002; Yoder and Standish, 1997). From the data of a GCM of the Martian atmosphere developed at the LMD in Paris, France (Forget et al., 1999), wind is found to induce rotation angle variations with an amplitude of 14 mas for the annual period and 76 mas for the semiannual period (Van den Acker et al., 2002). The contributions from atmosphere and ice cap loading are almost out of phase, with the atmosphere having an effect almost three times as large as that of the ice caps (Defraigne et al., 2000; Van den Acker et al., 2002). The effect of the ice caps is smaller than that of the atmospheric loading because mass at the polar ice caps has only a small contribution to the polar moment of inertia C, whereas atmospheric masses can be a Mars radius further from the polar axis and cause a larger change in the polar moment of inertia.

By neglecting the wind contribution and the small effects on rotation variations due to the elastic yielding of Mars and to the presence of a liquid core, LOD variations can most simply be obtained from the conservation of angular momentum $C\omega_3$. We here assume principal axis rotation, which is correct up to the first order in the rotation variations (see Section 10.04.2). The variation in the relative rotation rate is then proportional to the relative change in the largest moment of inertia C:

$$\frac{\Delta\omega_3}{\Omega} = -\frac{\Delta C}{C} \qquad [75]$$

From the definition of the gravitational coefficient $J_2 = [C - (A+B)/2]/MR^2$ and relation (Dobrovolskis, 1980) between rotation rate variations and LOD variations, we have

$$\frac{\Delta \mathrm{LOD}}{\mathrm{LOD}} = \frac{2}{3} MR^2 \frac{\Delta J_2}{C}. \qquad [76]$$

LOD variations can thus directly be determined from estimates of ΔJ_2. The contribution of the atmosphere to ΔJ_2 is about an order of magnitude smaller than that of the ice caps (Chao and Rubincam, 1990; Smith et al., 1999). LOD variations can then be determined from polar ice cap data only. In the approach with angular momentum functions described earlier, the atmosphere pressure is more important than the polar caps. This seemingly contradictory finding is due to fact that the difference between the terms in the ΔJ_2 approach indicates a difference in J_2, not in the rotation variations. To relate ΔJ_2 to rotation variations, mass conservation is assumed, which is not satisfied for the atmosphere or the ice caps separately. By using eqn [76], observational estimates of LOD variations can be obtained from several independent data. First, MGS, Odyssey, and MRO radio-tracking data have been used to estimate variations in the zonal degree-two coefficient of the gravitational field ΔJ_2 (Konopliv et al., 2006, 2011; Smith et al., 2001; Yoder et al., 2003). Secondly, the ice cap contribution to ΔJ_2 can be estimated from cap elevation changes up to 1.52 m measured with the onboard laser altimeter MOLA of MGS (Aharonson et al., 2004; Smith et al., 2001) and from the high-energy neutron detector (HEND, Litvak et al., 2004), the neutron spectrometer (NS) (Prettyman et al., 2009), and thermal imaging (Kieffer and Titus, 2001; Kieffer et al., 2000) instruments on board of Mars Odyssey. Best comparisons are between the LMD GCM and the NS data, but in general, differences are of the order of 10% (Karatekin et al., 2006a; Konopliv et al., 2011).

Besides loading and wind effects, also tides can induce rotation variations. Zonal tides change the moment of inertia C and so, by conservation of angular momentum, the length of day changes. From the change in C for a model with a decoupled liquid core (see also Yoder et al., 1981), amplitudes of the annual and semiannual tidally driven rotation angle variations were estimated by Yoder and Standish (1997) to be about 50 and 30 mas, respectively, or about one-tenth of the amplitudes induced by atmosphere and ice cap loading. Defraigne et al. (2000) numerically integrated the equation of motion, Poisson's equation, and the continuity equation from the center of the planet up to the surface (see Defraigne and Smits, 1999) to determine the rotational response of the planet to the zonal tides accurately determined by Roosbeek (1999). Elastic and inelastic mantles were considered, and the annual and semiannual rotation angle amplitudes are 15 and 8 mas, respectively. The difference between both models is on the order of 1 mas, at the limit of the expected future observational precision.

10.04.3.5 Polar Motion

10.04.3.5.1 Seasonal polar motion

Atmospheric dynamics and the condensation/sublimation cycle of the atmosphere and polar caps not only change the

rotation speed but also cause fluctuations in the orientation of the figure axis with respect to the rotation axis of Mars, partly because the polar caps are not symmetrical with respect to the rotation axis. Up to now, polar motion of Mars has not been measured directly. Theoretical model calculations have shown that the seasonal polar motion amplitudes are at most 20 mas, which is at the present-day detectability limits, but larger than the expected future precision of a few mas (e.g., Barriot et al., 2001; Defraigne et al., 2000; Konopliv et al., 2006; Yoder and Standish, 1997; Yseboodt et al., 2003).

The main atmospheric forcing is at seasonal frequencies, resulting in largest wobble amplitudes of about 10 mas at 1, 1/2, and 1/3 year, the exact values depending on the atmospheric and internal structure models used (Chao and Rubincam, 1990; Defraigne et al., 2000; Sanchez et al., 2004; Van den Acker et al., 2002; Yoder and Standish, 1997). The annual and semiannual wobble amplitudes, respectively, 13.6 and 11.2 mas, observationally determined by Konopliv et al. (2006) agree remarkably well with the theoretical values of 12.0 and 9.8 mas, respectively, of Van den Acker et al. (2002). The fact that the amplitude at 1/3 year is expected to be of the same order of magnitude as the amplitudes at 1 and 1/2 year is most likely due to the resonance with the Chandler wobble with a period of about 200 days (eqn [47], Dehant et al., 2003; Konopliv et al., 2006; Sanchez et al., 2004; Van Hoolst et al., 2000b; Yoder and Standish, 1997; Zharkov and Gudkova, 2005).

If Mars has a solid inner core, also the ICW period could be close to a seasonal forcing frequency, resulting in resonant polar motion amplification (Dehant et al., 2003). The degree of amplification is difficult to estimate and depends, among others, on the Q factor of the ICW, which is unknown. Nevertheless, the resonance strength for the ICW is very small, and a very close approach is needed for noticeable effects (Dehant et al., 2003, 2006).

10.04.3.5.2 Chandler wobble

Besides polar motion at seasonal frequencies, the Martian atmosphere could also excite the Chandler wobble. For the Earth, the Chandler wobble is the largest polar motion signal and is thought to be excited mainly by ocean bottom pressure fluctuations (Gross, 2000). Because Mars has no oceans and the Chandler wobble period for Mars ($P_{CW} \approx 200$ days) is far from the annual and semiannual periods where most excitation power of the atmosphere is expected (Dehant et al., 2006; Sanchez et al., 2004), the CW is not expected to have a large amplitude. From the spectral amplitude in the pressure recordings of the Viking landers near the CW period, Yoder and Standish (1997) estimated a CW amplitude of about 10 mas and possibly as large as 50 mas with ice loading excitation included. Dehant et al. (2006) estimated the power spectral density of the atmospheric excitation close to the CW period from the LMD GCM (Forget et al., 1999) and determined a CW amplitude between 30 and 100 mas for values of the quality factor Q between 80 and 300 (for estimates of the Q factor, see Bills et al., 2005; Smith and Born, 1976; Yoder, 1982). Other excitation sources such as marsquakes are too small (Golombek, 2002; Golombek et al., 1992) to excite polar motion to an observable level (Dehant et al., 2006).

From the observed variations in the order 1 gravity coefficients, and using ice cap models, Konopliv et al. (2006) determined an upper bound on the CW amplitude of about 10 mas. In their analysis based on MGS and Odyssey radio-tracking data, the CW signal in the gravity variations could not be isolated from the 1/3-year forced wobble. Unambiguous detection of the CW and determination of its period could be used to determine interior properties of Mars, although the CW period is mainly constrained by the global dynamic polar and equatorial flattenings of Mars. For an entirely rigid Mars, the CW period would be

$$P_{CW}^{rigid} = \frac{2\pi}{\Omega}\sqrt{\frac{AB}{(C-A)(C-B)}} = 190.8 \pm 0.3 \text{ days} \qquad [77]$$

(Konopliv et al., 2006), much smaller than the corresponding value for the Earth (about 304 days) because of the larger flattening of Mars. The true CW period is most likely between about 190 and 210 days (Dehant et al., 2003; Konopliv et al., 2006; Van Hoolst et al., 2000b; Yoder and Standish, 1997; Zharkov and Gudkova, 2005). The CW only weakly depends on the outer core and on the inner core. The core can have an influence on the order of a few days (Konopliv et al., 2006; Van Hoolst et al., 2000b), and the changes induced by the inner core are smaller than the uncertainty on the global dynamic flattening (Dehant et al., 2003). Large mantle anelasticity (Q-values below 100) could increase the period by up to about 7 days (Van Hoolst et al., 2000b). Uncertainties in the rigidity and compressibility profiles also affect the Love number k_2 and therefore the CW period (see eqn [47]). For large changes of 10% and 21% in the mantle seismic velocities V_P and V_S with respect to a standard model, the CW period changes by about 0.5 days and 5 days, respectively (Van Hoolst et al., 2000a). To derive interior properties of Mars from the CW period, its future observational accuracy must therefore be at least about 1 day.

10.04.4 Venus

10.04.4.1 Current Rotation State

The analyses of radar observations of Venus during its inferior conjunction in fall 1962 showed that Venus rotates retrogradely with a period of about 250 days about an axis nearly perpendicular to its orbit (Carpenter, 1964; Goldstein, 1964). This period is close to the 243.16-day period for the synodic resonance with the orbital motion of the Earth, in which Venus would show exactly the same face to the Earth at each inferior conjunction and would rotate exactly five times as seen from the Sun between consecutive inferior conjunctions, suggesting that Venus might occupy that resonance (Gold and Soter, 1969; Goldreich and Peale, 1966a,b). Further observations with the Goldstone, Arecibo, and Haystack radar systems yielded an improved period of 243.026 ± 0.006 days (Carpenter, 1966, 1970; Dyce et al., 1967; Shapiro et al., 1990), and the analyses of Magellan data have led to an averaged rotation period of 243.0185 ± 0.0001 days based on radar images (Davies et al., 1992) and of 243.0200 ± 0.0006 days based on X-band radio-tracking data (Konopliv et al., 1993, 1999), all three very close to but not exactly equal to the resonance period of 243.16 days. The analyses of Magellan radar data show that the current obliquity of Venus is about 2.6° (or 177.4°) (Davies et al., 1992; Yoder, 1995).

10.04.4.2 Long-Term Spin Evolution

The long rotation period and the retrograde rotation and the almost perpendicular position of Venus with respect to its orbital plane could be primordial. More plausibly however, the rotation of Venus has changed over time. The dissipation of tides in Venus raised by the Sun causes a delay in the appearance of the tidal bulge of Venus, and the solar torque on it tends to decrease the rotation period of Venus and to drive Venus to a 1:1 resonance with its orbital motion on a timescale of 10^8 years to 10^9 years (Correia and Laskar, 2003a; Dobrovolskis and Ingersoll, 1980; Yoder, 1995). Venus' slow rotation can therefore not be taken as an indication for a primordial slow rotation. Instead of being locked in a spin–orbit or spin–synodic resonance, the rotation of Venus is thought to be the result of a balance between solid-body tidal torques, which drive Venus to synchronous rotation, and atmospheric torques, which drive it away (Correia and Laskar, 2001; Correia and Laskar, 2003a, 2003b; Correia et al., 2003; Dobrovolskis, 1980; Dobrovolskis and Ingersoll, 1980; Gold and Soter, 1969; Kundt, 1977; Lago and Cazenave, 1979; McCue and Dormand, 1993; Shen and Zhang, 1989; Yoder, 1995). For the Earth, the thermal tides are too small to balance the tidal gravitational dissipation, but Venus has a much denser atmosphere and, most likely, a smaller tidal dissipation due to the absence of oceans. The acceleration of the Earth's rotation due to the thermal tides is about three times smaller than the deceleration due to the solar gravitational torque and less than 10% of the total solid-body gravitational effect including the Moon (Munk and MacDonald, 1960).

For a fast initial rotation ($\omega \gg n$), both the gravitational tides and friction at the CMB decelerate the rotation of Venus, whereas the atmospheric thermal tides that tend to accelerate Venus are small and their contribution to the rotation rate can be neglected. Once the slow rotation regime ($\omega \sim n$) has been reached, the core–mantle friction torque dominates the obliquity evolution and drives Venus to an orientation with its polar axis perpendicular to its orbital plane for a wide range of values for the dissipative parameters (Correia and Laskar, 2001; Correia et al., 2003; Goldreich and Peale, 1970; Yoder, 1995). For such a final orientation, core–mantle friction does not affect the rotation rate anymore, and thermal atmospheric tides can balance the solid-body tidal braking effect. Starting from a prograde initial rotation, Venus may have evolved according to one of the following two different rotation histories. In the first scenario, Venus' rotation axis flips direction under the influence of atmospheric torques and slows down (Dobrovolskis, 1980; Lago and Cazenave, 1979; McCue and Dormand, 1993; Shen and Zhang, 1989; Yoder, 1995). In the second scenario, Venus slows down while changing its obliquity to 0° and then develops a retrograde rotation (Correia et al., 2003; Kundt, 1977). The current rotation state of Venus therefore places no constraints on the primordial spin.

Correia and Laskar (2001, 2003a) have extensively tested the long-term evolution of the spin of Venus in realistic simulations that include the planetary perturbations. Without planetary perturbations, a final rotation state with $\varepsilon = 180°$ is only possible for sufficiently large initial obliquities and a dominant atmospheric torque (Correia and Laskar, 2001; Dobrovolskis, 1980; Lago and Cazenave, 1979; McCue and Dormand, 1993; Shen and Zhang, 1989; Yoder, 1995). Planetary perturbations can lead to large chaotic changes in the obliquity of Venus as a result of resonance overlap between the precession frequency and combinations of secular frequencies of changes in the orbital plane of Venus (Laskar and Robutel, 1993; Yoder, 1995). Based on eqn [5] for the precession rate and possible values for the polar moment of inertia, the current precession rate of Venus has been estimated to be about 45 arcsec year^{-1}, corresponding to a precession period of about 28 800 years (Yoder, 1997). If Venus initially had an obliquity lower than 90° and a rotation period shorter than 5 days, it could not have escaped the chaotic zone, which lies between 0° and 90° (Correia et al., 2003). As a result, Venus could have reached the final retrograde state with obliquity $\varepsilon = 180°$ starting from any initial obliquity (Correia and Laskar, 2001, 2003a; Correia et al., 2003; Yoder, 1997). Planetary perturbations largely increase the probability of reaching a retrograde final state and make it the most probable final state for small initial rotation periods (< 5 days) or high initial obliquities (Correia and Laskar, 2001, 2003a; Correia et al., 2003).

In the presence of planetary perturbations, capture into the 1:1 spin–orbit resonance becomes unlikely and the obliquity never goes to zero (Correia and Laskar, 2001, 2003a; Correia et al., 2003). Small forced obliquity changes up to a few degrees are possible and are associated with small changes in the rotation rate (Correia et al., 2003; Yoder, 1995). Therefore, with planetary perturbations included, the final states are no longer steady states. The current obliquity of Venus is 2.6° (Davies et al., 1992; Yoder, 1995). Planetary-induced changes in the eccentricity of the orbit of Venus can also lead to long periodic changes in the rotation rate. Because the strengths of the tidal gravitational and thermal atmospheric torques have different dependencies on the radial distance from the Sun, changes in the eccentricity cause slight imbalances in these torques. The resulting rotation velocity changes can be up to a few km year^{-1} at the equator, over timescales of 10^6 years (Bills, 2005b).

10.04.4.3 Wobble, Length-of-Day Variations, and Nutation

A departure of the mean position of the polar principal moment of inertia axis of Venus from the rotation axis has been determined from coherent two-way radio-tracking data of the Pioneer Venus Orbiter (PVO, 1978–92) and Magellan (1990–94). First results suggested a large orientation difference of a few degrees (Bills et al., 1987; Mottinger et al., 1985), much larger than the wobble amplitudes for the Earth and Mars, which are below an arcsec (Munk and MacDonald, 1960, **Section 10.04.3**). Later studies including Magellan data gave estimated values of about 0.5° (Konopliv and Sjogren, 1994; Konopliv et al., 1993, 1999; McNamee et al., 1993), although Nerem et al. (1993) (see also Konopliv et al., 1993), who only used PVO data, obtained an even smaller amplitude of about 0.1°. Konopliv and Sjogren (1994) quote a formal error of 0.05° for the pole position.

Due to the slow rotation of Venus, $J_2 = (4.404 \pm 0.002) \times 10^{-6}$ (Konopliv et al., 1999) is much smaller than for the Earth and not dominated by the contribution from rotation, which is on the order of 10^{-8}. The equatorial flattening is equally small,

with $(B-A)/MR^2 = 4C_{22} = (2.215 \pm 0.003) \times 10^{-6}$. Because of these small flattenings and the long rotation period, the Chandler wobble has a very long period. In the rigid approximation, we have

$$P_{\mathrm{CW}}^{\mathrm{rigid}} = \frac{2\pi}{\Omega}\sqrt{\frac{AB}{(C-A)(C-B)}} \approx 50,000 \text{ years} \qquad [78]$$

(Mottinger et al., 1985). Elasticity tends to increase this period by less than 1% ($k_2 = 0.295 \pm 0.066$, Konopliv and Yoder, 1996), whereas a liquid core would decrease the period by about 10%, depending on the size and density of the core (see eqn [47]). The relative effect of elasticity is much smaller than the almost 50% increase of the CW for Earth due to elasticity (Smith and Dahlen, 1981) because the polar flattening of Venus (or J_2) is mainly due to nonhydrostatic effects and not to rotational flattening as for the Earth. The deformation associated with the Chandler wobble, due to the differential rotation and the resulting centrifugal potential, then has a very small effect on the mean inertia moments and almost does not change the effective flattening. In eqn [47] for the Chandler wobble period, the term k_2/k is then very small compared to 1. The slow rotation of Venus also implies a much less efficient damping than on Earth (Yoder and Ward, 1979). A larger CW amplitude than for the Earth would then be possible even for a smaller excitation rate than that required to maintain the Earth's CW. Excitation could be due to seismic activity, mantle convection, or atmosphere/climate variations. By assuming quake-induced ΔC_{21} comparable to the Earth, Yoder and Ward (1979) estimated that a wobble amplitude $< 1^\circ$ requires a seismic activity rate on Venus $\leq 10^{-2}/Q(\sigma_{\mathrm{CW}})$ times the rate of seismic activity on the Earth. The small observed wobble suggests that Venus is significantly less active than the Earth (Yoder, 1995, 1997).

Short periodic LOD variations and orientation changes in space (nutation) have not yet been observed and are expected to be small. Because of the almost perpendicular position of Venus' rotation axis with respect to the orbital plane (see **Table 1**), Venus does not have seasons as on the Earth and Mars, for which the seasonal atmospheric cycle is the main driver of LOD variations. Periodic LOD variations of Venus have been calculated theoretically from GCMs of the atmosphere of Venus, which show that changes in the angular momentum of Venus are of the same order of magnitude as on Earth but have a main period equal to the solar day of 117 days as a result of variations in the received solar radiation (Karatekin et al., 2011; Lebonnois et al., 2010). Since the solid-body angular momentum of Venus is two orders of magnitude smaller than for the Earth because of Venus' slower rotation, larger rotation variations might be expected on Venus, but the induced surface displacements are only a few meters because of this slow rotation. The LOD variations are mainly driven by the wind, as for the Earth but in contrast with Mars (Karatekin et al., 2011).

Nutations on Venus are expected to be somewhat smaller than on Earth. The solar torque, which causes the nutations, is much smaller than for the Earth mainly because the polar flattening is a factor 250 smaller (Konopliv and Yoder, 1996). The differences with respect to the Earth due to Venus' small obliquity and shorter distance to the Sun are much less significant. The shorter distance to the Sun would tend to increase the nutations by a factor 2.6, and the small obliquity (see the $\sin 2\delta$ in eqns [65] and [66]) reduces the nutation amplitudes with respect to the Earth by a factor of 8. On the other hand, the slow rotation of Venus implies a weaker rotational stability, and orientation changes such as nutation are larger for a given torque (see also eqns [63] and [64]), which almost compensates for the smaller torque. The small eccentricity of the orbit of Venus suggests that nutations other than the semiannual nutation would be smaller.

For the Earth and Mars, nutation observations have and can be used to determine properties of the deep interior of these planets. For Venus, however, nutations observations have less geophysical potential because resonance effects with the FCN are expected to be negligible. The FCN period is about 10^5 years in inertial space (we assumed a similar CMB flattening as for the total planet and neglected the very small effect of deformation), far from the main nutation excitation periods, which are associated with Venus' orbital motion.

10.04.5 Mercury

10.04.5.1 Current Rotation State

Based on radar observations of the rotation of Mercury made at the Arecibo Observatory in Puerto Rico (Pettengill and Dyce, 1965), Colombo (1965) proposed the idea that Mercury has a stable rotation period exactly equal to 2/3 of the orbital period. This 3:2 spin–orbit resonance is now universally accepted. Before, it was thought that Mercury's spin was in a 1:1 resonance with its orbital motion, just like the Moon in its orbit around the Earth (see, e.g., Chapman, 1988). The rotation period of Mercury is 58.64601 days (Margot, 2009).

Mercury closely occupies the Cassini state 1, in which the rotation axis and the orbit normal remain coplanar with the normal to the Laplace plane as the rotation axis of Mercury precesses about the orbit normal and the orbit normal precesses about the normal to the Laplace plane (Colombo, 1966; Margot et al., 2007; Peale, 1969; Ward, 1975). The Laplace plane is defined as the plane about which Mercury's orbit precesses with constant inclination between the two planes. A Cassini state represents an extreme (equilibrium point) in the Hamiltonian of motion, made integrable by limiting the planetary perturbations (mainly due to Venus, the Earth, and Jupiter) to a single term corresponding to a regular motion of the ascending node, and has first been determined empirically for the Moon (Cassini, 1693). Observational evidence for this state has been obtained by Margot et al. (2007). From the observations of the determination of the epoch and time delay that maximize the cross correlation of the backscattered radar signal at two antennas separated by a long baseline (Holin, 1999), Margot et al. (2012) had shown that the spin pole position differs by 2.7 arcsec from the prediction Cassini 1 position, within the 5 arcsec uncertainty on the orientation. The obliquity of Mercury is 2.4 ± 0.08 arcmin (Margot et al., 2012).

10.04.5.2 Long-Term Spin Evolution

10.04.5.2.1 Spin–orbit resonance

Because of Mercury's closeness to the Sun, tidal friction can slow down the rotation of Mercury to rotation periods

commensurate with the orbital period on a timescale much smaller than the age of the solar system (see eqn [58]). Correia and Laskar (2004) estimated that the time needed to despin Mercury from an initial rotation period of 10 h would be about 300 Ma for a Q-value of 50. The final equilibrium rotation period for Mercury is different from the rotation synchronous with the orbital motion expected for tidal despinning of planets in circular orbits because of Mercury's substantial eccentricity. If the rotation were synchronous, the angular rotation rate would be smaller than the orbital velocity close to perihelion and larger near to aphelion, resulting in accelerating and decelerating tidal torques, respectively. Because of its distance dependence, the tidal torque is larger near perihelion than at aphelion, and the mean tidal torque would act to spin up Mercury. For the present eccentricity ($e=0.206$), the equilibrium rotation velocity is $\omega=1.25685n$, and the present mean rotation rate of Mercury ($3n/2$) corresponds to the tidal equilibrium rotation rate for eccentricity $e_{3/2}=0.284927$ (Correia and Laskar, 2004, who assume the averaged tidal torque to be linear in the tidal frequency). The tidal torque equilibrium is currently not satisfied because Mercury is locked in the 3:2 spin–orbit resonance.

We here assume zero obliquity (the observed value is (2.04 ± 0.08) arcmin, Margot et al., 2012) and principal axis rotation for the study of Mercury's rotation rate. Only the z-component of the Liouville equations must then be considered. For an entirely solid and rigid planet, eqn [25] reduces to

$$C\Omega\dot{m}_z = L_P \qquad [79]$$

where

$$L_P = \frac{3}{2}(B-A)\frac{GM_\odot}{r^3}\sin 2\xi \qquad [80]$$

is the solar torque on Mercury's permanent figure. We for the moment neglect the tidal torques. The distance r is the distance between the mass centers of the Sun and Mercury, and ξ is the angle between the direction of Mercury's axis of smallest moment of inertia A (also called the long axis) and the direction to the Sun:

$$\xi = f - \phi \qquad [81]$$

where f is the true anomaly and ϕ the rotation angle between the long axis of Mercury and the major axis of Mercury's orbit considered fixed (see Figure 3). We consider a rotation close to the 3:2 spin–orbit resonance and introduce the angle $\gamma=\phi-\frac{3}{1}M$, where M is the mean anomaly. At perihelion passage, γ is the angle between the direction of Mercury's long axis and the direction to the Sun. From the definitions of the angles γ and ξ, we have

$$\xi = f - \gamma - \frac{3}{2}M \qquad [82]$$

and the torque equation can be expressed as

$$C\ddot{\gamma} = -\frac{3}{2}n^2(B-A)\frac{a^3}{r^3}\sin(2\gamma+3M-2f) \qquad [83]$$

where the mean motion $n=\sqrt{G(M_\odot+M_{Merc})/a^3}\approx\sqrt{GM_\odot/a^3}$ is used. The time-dependent factor $\frac{1}{r^3}\sin(2\gamma+3M-2f)$ of the torque can be expanded in terms of the mean anomaly M as

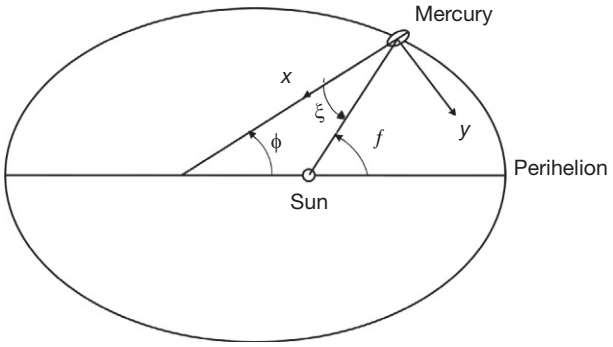

Figure 3 Geometry of Mercury's spin–orbit motion. Mercury's long axis makes an angle ξ with respect to the Sun and an angle ϕ with respect to an inertial reference axis, here taken to be temporarily coinciding with the semimajor axis of Mercury's orbital motion around the Sun.

$$\frac{1}{r^3}\sin(2\gamma+3M-2f) = \frac{1}{a^3}\sum_q G20_q(e)\sin[2\gamma+(1-q)M] \qquad [84]$$

(e.g., Murray and Dermott, 1999), where $G_{20q}(e)$ are eccentricity functions (Kaula, 2000). By developing the sine terms and retaining only terms up to e^4 in the eccentricity functions, we have

$$\begin{aligned}&\frac{d^2\gamma}{dM^2}+\frac{3}{4}\frac{B-A}{C}e\left(7-\frac{123}{8}e^2\right)\sin 2\gamma\\&=-\frac{3}{2}\frac{B-A}{C}\left[\left(1-11e^2+\frac{959}{48}e^4+\cdots\right)\sin M\right.\\&\left.-\frac{1}{2}e\left(1+\frac{421}{12}e^2+\cdots\right)\sin 2M+\cdots\right]+\cdots\end{aligned} \qquad [85]$$

(Peale, 2005). The angle γ is considered very small, and time-dependent forcing terms proportional to sin 2γ have been neglected compared to the other terms in the right-hand side.

For the study of the stability of the 3:2 resonance, eqn [85] is averaged over an orbital period. Since the torques are small, ξ does not change much over an orbital period, and $\dot{\xi}$ (or $\dot{\gamma}$) can be kept constant in the averaging procedure. The periodic forcing terms in the right-hand side of eqn [85] then vanish, and the equation reduces to the harmonic oscillator (or pendulum) equation:

$$\frac{d^2\gamma}{dM^2}+\frac{3}{4}\frac{B-A}{C}e\left(7-\frac{123}{8}e^2\right)\sin 2\gamma = 0 \qquad [86]$$

which has $\gamma=0$ as a stable solution. This solution corresponds to the long axis of Mercury pointing toward the Sun at perihelion.

The effect of tidal dissipation can be included by adding the averaged tidal torque $<L_T>$ divided by n^2C to the right-hand side of eqn [85]. If $<L_T>$ can be assumed to be constant (independent of $\gamma,\dot{\gamma},t$), the stability of the 3:2 resonance is maintained if the averaged tidal torque does not exceed the maximum possible restoring torque:

$$|<L_T>| < \frac{3}{4}(B-A)n^2e\left(7-\frac{123}{8}e^2\right) \qquad [87]$$

(Colombo and Shapiro, 1966; Goldreich and Peale, 1966b). By using eqn [56], this translates into a condition on the permanent deformation and the tidal dissipation factor Q:

$$\frac{B-A}{4MR^2} > \frac{k_2}{14Q}\left(\frac{R}{a}\right)^3 \frac{M_\odot}{M}\frac{1+\frac{123}{56}e^2}{e} \approx \frac{7\times 10^{-8}}{Q}, \qquad [88]$$

where we used $k_2 \approx 0.4$ (Rivoldini et al., 2009; Spohn et al., 2001; Van Hoolst and Jacobs, 2003; Van Hoolst et al., 2007). Given that the moment of inertia difference $B-A = (3.235\pm0.024)\times10^{-5}MR^2$ (Smith et al., 2012) and that Q is in the range from 10 to 500 (Goldreich and Soter, 1966), this stability condition is certainly satisfied. For a circular orbit, the 3:2 resonance would not be stable. Note that a large equatorial flattening and a large eccentricity contribute to the stability of the resonance. Several other resonances in the vicinity of the 3:2 resonance are also stable (Goldreich and Peale, 1966b). Why then did Mercury select the 3:2 resonance?

A necessary condition for capture is that the averaged tidal torque is not symmetrical about $\dot{\gamma}=0$; otherwise, a decelerating Mercury would continue to decrease its rotation rate (Goldreich and Peale, 1966b; Peale, 1976a). If the phase lag is proportional to the tidal frequency (Q inversely proportional to tidal frequency), this condition is satisfied. Even for constant Q dissipation models, the torque depends on the sign of the phase angle (or the sign of $\dot{\gamma}$, e.g., Kaula, 1964), and it can be concluded that the averaged tidal torque is expected to be asymmetrical about $\dot{\gamma}$ for all tidal models (Goldreich and Peale, 1966b). The precise capture probability is quite model-dependent. Assuming the dissipation factor to be inversely proportional to the frequency, Goldreich and Peale (1966b) found that Mercury has the largest probability to be captured in the 3:2 resonance, with a probability of 6.7%. The capture probability is rather small but can be increased if dissipative core–mantle coupling is included. Other resonances will then also have increased capture probabilities, and specific core viscosity values are needed to avoid capture in the 2:1 resonance (Peale and Boss, 1977). In these calculations, the present value of the eccentricity was used. However, Mercury's eccentricity shows large chaotic variations in time between zero and about 0.5 due to planetary influences (Laskar, 1994). As a result, over time, Mercury's eccentricity could have passed several times through the value $e_{3/2}$ at which tidal torques tend to drive Mercury's rotation velocity to the 3:2 resonant value, thereby considerably increasing the capture probability (Correia and Laskar, 2004). Moreover, Mercury could have escaped from an initial resonance capture when the eccentricity decreased to low values close to zero. The probability that the 3:2 spin–orbit resonance is the final state is 55.4% for a solid core (Correia and Laskar, 2004) and reduces to 22.6% for a liquid core (Correia and Laskar, 2009). However, large impacts may have disrupted any initial resonant capture and changed the final rotation state. The asymmetrical distribution of large impact basins is consistent with a previous synchronous rotation of Mercury, which is the most likely outcome for an initial retrograde rotation of Mercury. By including the effects of impacts, Correia and Laskar (2012) had shown that for both prograde and retrograde initial rotations, the 3:2 resonance is the most likely end state with a probability of around 50% and that the synchronous state is the second most probable.

10.04.5.2.2 Precession about the Cassini state and nutation

Tidal friction drives the spin of Mercury to Cassini state 1 from almost any initial condition on a timescale that is short compared to the age of the solar system (Peale, 1974). The primordial obliquity of Mercury was probably below 90°; otherwise, core–mantle friction could have driven Mercury to the Cassini state 3, similar to Cassini state 1 but with an obliquity 180° larger (Peale, 1976a). Provided that Mercury was born as a fast rotator, it must have passed a large chaotic zone in which the obliquity shows large and chaotic variations of tens of degrees within a few million years (Laskar and Robutel, 1993). The obliquity of the final evolved Cassini state 1 is given by

$$\frac{C}{MR^2} = \frac{\left[\frac{J_2}{(1-e^2)^{3/2}} + eC_{22}\left(7-\frac{123}{8}e^2\right)\right]}{\frac{\sin I}{\varepsilon_C}+\cos I}\frac{n}{\mu} \qquad [89]$$

(Peale, 1969), where ε_C is the obliquity of Cassini state 1, $I=8.6°$ the inclination of the orbital plane to the Laplace plane (Seidelmann, 2005), and $\mu = 2\pi/(328\,000$ years) the precession rate of Mercury's orbit about the normal to the Laplace plane (Yseboodt and Margot, 2006). Because the rotation axis is coplanar with the orbit normal and the normal to the Laplace plane in a Cassini state, the obliquity of the rotation axis is constant. For the recently determined degree-two gravitational coefficients from MESSENGER radio tracking ($J_2 = (5.03\pm0.02)\times10^{-5}$ and $C_{22} = (0.809\pm0.006)\times10^{-5}$, Smith et al., 2012) and the observed obliquity of (2.04 ± 0.08) arcmin (Margot et al., 2012), eqn [89] shows that $C/MR^2 = 0.346\pm0.014$, putting a strong constraint on Mercury's interior structure (Hauck et al., 2013; Rivoldini and Van Hoolst, 2013; Smith et al., 2012). Note that the large C_{22} and J_2 values compared to those expected for a hydrostatic Mercury with the current rotation rate and 3:2 spin–orbit resonance could be explained by a large remnant bulge caused by an initial faster rotation and subsequent polar wander due to the formation of the Caloris impact basin (Matsuy-Mama and Nimmo, 2009).

The precession period of both the orbit normal and the rotation axis around the normal to the Laplace plane is about 328 000 years (Yseboodt and Margot, 2006). Besides the slow precession of the orbit normal and the rotation axis around the normal to the Laplace plane, the rotation axis of Mercury also precesses about its position in the Cassini state if Mercury does not exactly occupy but is close to the Cassini state (Peale, 1974; Rambaux and Bois, 2004; Ward, 1975). If we neglect the much slower orbital precession, the latter precession due to the solar torque (also called free precession) can be compared to the precession of the Earth about the normal to the ecliptic. However, due to Mercury's 3:2 spin–orbit resonance, the classical analytic expression for the precession rate (see, e.g., Smart, 1953) must be extended with a term in the equatorial flattening (or C_{22}). By averaging the Liouville equations without deformation effects over the orbital period, the precession period can be derived, correct up to order e^3, as

$$P_{\text{Prec}} = \frac{3\pi C^m}{nMR^2}\left\{\left[\frac{3J_2}{2(1-e^2)^{3/2}} + \frac{3}{2}eC_{22}\left(7-\frac{123}{8}e^2\right)\right]^2 - C_{22}^2\frac{159}{16}e^6\right\}^{-1/2} \quad [90]$$

(Peale, 2005). The C_{22} terms decrease the traditional precession period by nearly 30% and cause the precession motion to be slightly elliptical (Peale, 2005). For a solid core, $C = 0.346MR^2$, and the MESSENGER gravitational coefficients (Smith et al., 2012), the precession period is 1297 years. However, at least the outer part of Mercury's core is liquid as follows from Mercury's libration observations (Margot et al., 2007; see next section) and $C^{\text{m}}/(MR^2)$ is estimated to be 0.148 ± 0.006 (next section). The precession period is then estimated to be 556 years, shorter than for an entirely solid Mercury, as expected for short periodic mantle precession.

Tidal friction and dissipative core–mantle coupling will damp free precession, that is, will reduce the obliquity variations, and will drive the rotation axis to the Cassini state if the orbital inclination to the invariable plane is fixed and Mercury precesses about the Cassini state at constant rate (Peale, 1974, 2005; Ward, 1975). Because of planetary perturbations, the precession rate and inclination show large variations, which suggests that Mercury cannot remain exactly in the Cassini state. However, the precession period is much smaller than the shortest timescales of about 10^4 to 10^6 years for the variations in the planetary orbital parameters. Therefore, the rotation axis accurately tracks the changes in the orientation of the orbit normal. If Mercury has once been driven close to the Cassini state by dissipative effects, it is expected to remain very close to the instantaneous location of the Cassini state (Goldreich and Toomre, 1969; Peale, 1974). With a typical core viscosity value for the Earth's core determined from ab initio calculations (de Wijs et al., 1998) and $Q \approx 100$, Peale (2005) obtained free precession damping timescales of about 10^5 years. This is much shorter than the age of the solar system, suggesting that free precession is either completely damped or recently excited (Peale, 1974; Ward, 1975). On the other hand, the damping timescale is somewhat longer than the 10^4-year timescale of the Laplace plane reorientation, and the changing Cassini state may never be reached exactly, but nevertheless, the rotation axis remains close to the Cassini state, even if the Cassini obliquity changes due to the precession of the orbit (Yseboodt and Margot, 2006). Peale (2006) followed the spin position and the Cassini state position during short timescale orbital variations over 20 000 years as well as during long timescale variations over the past 3 My and showed that the spin axis remains within one arcsec of the Cassini state if it initially occupied the Cassini state. On the other hand, Bills and Comstock (2005) obtained obliquity variations forced by the orbital motion on timescales of My with typical obliquity values of 2–4 arcmin, values that are larger than the observed obliquity. The obliquity history looks very much like a scaled version of the inclination history, with the obliquity variations being roughly 200 times smaller than the corresponding inclination variations and typical periods of about 100 ky and 1 My (Bills and Comstock, 2005).

Another source of possible deviations from the Cassini state is short periodic variations in obliquity and longitude caused by the solar torque. These variations, similar to the nutations for the Earth and Mars, have main frequencies equal to the harmonics of the orbital frequency (Carpentier and Roosbeek, 2003). The amplitudes are on the order of 0.1 arcsec or smaller (Carpentier and Roosbeek, 2003; Rambaux and Bois, 2004). They have been calculated for a rigid Mercury, but are not expected to be largely amplified when the interior properties of Mercury are taken into account. For the Earth and Mars, the FCN frequency is close to the main nutation frequencies, and some nutations are resonantly amplified. For Mercury, the FCN period is at least several hundred years, as can be estimated from eqn [48], and is far from the period of the nutations.

10.04.5.3 Librations

10.04.5.3.1 Forced libration

Because of the gravitational torque on the permanent figure of Mercury in its elliptical orbit, the rotation of Mercury is not constant and varies about a mean state. For the analysis of these librations, we include the liquid core, but still neglect deformation (no incremental inertia terms). Liouville eqns [25] and [37] can then be written as

$$C\Omega\dot{m}_z + C^{\text{f}}\Omega m_z^{\text{f}} = \frac{3}{2}(B-A)\frac{GM_\odot}{r^3}\sin 2\xi \quad [91]$$

$$C^{\text{f}}\Omega\left(\dot{m}_z + \dot{m}_z^{\text{f}}\right) = 0 \quad [92]$$

where the last equation indicates that the core does not follow the rotation variations, or librations, of the mantle. By substituting eqn [92] into eqn [91], and taking into account that $C = C^{\text{m}} + C^{\text{f}}$, the Liouville equation for the whole planet can be transformed to a Liouville equation for the mantle:

$$C^m\ddot{\gamma} = \frac{3}{2}(B-A)\frac{GM_\odot}{r^3}\sin 2\xi \quad [93]$$

where the libration γ is now defined in terms of the direction of the long axis of the mantle. With inclusion of a liquid core, the only change in eqns [83] and [85] is that C must be replaced by C^{m}. Equation [85] with C replaced by C^{m} is an equation for a forced harmonic oscillator describing forced libration in longitude. The angle γ is usually called the libration angle. The forcing is at 1 orbital period, 1/2 orbital period, and higher subharmonics of the orbital period, which have been neglected here. Due to the small ratio $(B-A)/C^{\text{m}}$, the amplitude γ_1 of the 88-day libration is equal to the amplitude of the sin M term in eqn [85]:

$$\gamma_1 = \frac{3}{2}\frac{B-A}{C^{\text{m}}}\left(1 - 11e^2 + \frac{959}{48}e^4 + \cdots\right) \quad [94]$$

(Peale, 1972), and the amplitude of the sin $2M$ term is about 11% of that (Jehn et al., 2004; Van Hoolst et al., 2012). Because of its dependence on the mantle moment of inertia, the forced libration amplitude offers a unique opportunity to study the deep interior of Mercury. Mantle must be understood here as the solid part of the planet above the liquid core that partakes in the libration and thus also includes the crust.

Margot et al. (2012) determined the amplitude of the 88-day libration to be (38.5 ± 1.6) arcsec, which corresponds

to a maximum displacement at the equator with respect to the equilibrium rotation of (455 ± 19) m. For the MESSENGER $B-A$ value (Smith et al., 2012), eqn [94] shows that $C^m/(MR^2) = 0.148 \pm 0.006$ (Margot et al., 2012; Rivoldini and Van Hoolst, 2013), less than half the value for the total planetary moment of inertia $C/(MR^2) = 0.346 \pm 0.014$ determined from the obliquity value. Therefore, Mercury cannot be entirely solid, and a global liquid layer must exist relatively much closer to the surface than, for example, the fluid outer core of the Earth that is separated from the surface. The comparison of the rotational constraints on C and C^m with theoretical moment of inertia values for models of the interior structure of Mercury shows that the liquid core has a radius of about 2000 km (Hauck et al., 2013; Rivoldini and Van Hoolst, 2013; Smith et al., 2012).

For a correct interpretation of libration observations, all possible effects on the rotation angle variations of Mercury have to be quantified, such as the effect of neglected deformation and core–mantle couplings in eqn [94]. These effects have been shown to be important for changes in the rotation angle of the Earth. For example, on a decadal timescale, the changes in the rotation angle of the Earth are attributed to the exchange of angular momentum between the core and the solid mantle (Jault et al., 1988), but there is no general agreement on which physical mechanism dominates.

Electromagnetic coupling between the core and the mantle arises from the flow of electric current in the weakly conducting mantle. The mantle conductivity is assumed to be concentrated in a thin layer at the CMB, possibly resulting from chemical reactions between the mantle silicates and the conducting liquid iron assemblage (Buffett et al., 2000). Holme (1998) showed that electromagnetic coupling is capable of explaining the observed changes in the rotation rate of the Earth. Peale et al. (2002) applied Buffett's (1992) formalism for electromagnetic coupling to Mercury and estimated the torque related to the poloidal magnetic field from Mercury's observed magnetic dipole moment of $6 \times 10^{12}\,\mathrm{Tm}^3$ as estimated from Mariner 10 data (Russell et al., 1988; note that the new MESSENGER estimate of Anderson et al., 2012, does not affect the conclusions). The time constant for the decay of the relative angular velocity between the core and the mantle due to the electromagnetic torque is estimated to be on the order of 10^6 years. As this is much larger than the 88-day period of the forced libration, the electromagnetic torque does not affect the forced libration (Peale et al., 2002). The torque could, however, be larger, and the decay time smaller, since only the observed dipole moment is used in the calculation and the torque involving the toroidal magnetic field has been neglected. As the dynamo action in Mercury is not well understood and different mechanisms have been proposed (e.g., Christensen, 2006; Manglik et al., 2010; Takahashi and Matsushima, 2006; Vilim et al., 2010), it cannot be excluded that the dipole field of Mercury is even very small compared to the total magnetic field in the core. For example, Stanley et al. (2005) showed that thin shell dynamos, which could be applicable to Mercury, can produce magnetic fields of different geometry than the Earth's magnetic field and with Mercury-like dipolar field intensities. The toroidal field strength can be 100 times larger than the dipolar strength, and the poloidal field strength can be 10 times larger than the dipolar strength. Projecting the dipole field observed by Mariner 10 and MESSENGER to the CMB then does not provide a good estimate for the CMB field.

Pressure coupling between the liquid core and the mantle requires a nonspherical interface. Due to the 3:2 spin–orbit resonance, static tides will induce a small difference in the long and short equatorial axes. These differences are, however, very small and of the order of a meter (Matsuyama and Nimmo, 2009). Mantle convection (e.g., Schubert et al., 1988), if it still is operational (Grott et al., 2011; Michel et al., 2012; Reese and Peterson, 2002), induces further topography on the CMB. In the thin Mercurian mantle, convection cells with relatively small horizontal length scales comparable to the mantle depth become unstable for the lowest Rayleigh numbers (Schubert et al., 2001). The resulting deviations from the hydrostatic equilibrium form are not expected to contribute largely to B^f-A^f, although some models suggest that convection might be organized in convection cells of large horizontal scale (Conzelmann and Spohn, 1999). As the shape of the CMB is essentially unknown, Peale et al. (2002) rescaled the topographic torque on the Earth's mantle needed to explain the Earth's LOD variations to Mercury in order to estimate the effect of topographic pressure coupling on Mercury's librations and showed that the change in the forced libration is essentially undetectable (Peale et al., 2002). Inertial coupling on the nonspherical CMB also has a negligible effect (Rambaux et al., 2007), and viscous coupling at the CMB can be neglected too since the relaxation timescale for relative motion between the mantle and the liquid core is several orders of magnitude longer than the 88-day period of libration for any reasonable value for the core viscosity.

An inner core can also interact directly with the mantle through gravitational coupling if the long axes of inner core and mantle are not aligned and influence the mantle libration. The global magnetic field observed by Mariner 10 and MESSENGER, if caused by dynamo action, not only is further evidence for a liquid outer core but also suggests that Mercury contains a growing solid inner core (Schubert et al., 1988; Spohn, 1991; Stevenson et al., 1983). The inner core is possibly even relatively large (Grott et al., 2011; Hauck et al., 2004; Stevenson et al., 1983) although its size is limited by the global radial contraction of 2.4–3.6 km estimated from Mercury's tectonics (Di Achille et al., 2012). The effect of an inner core on Mercury's 88-day libration amplitude has been shown to be below the observational precision for small inner cores but could be observed with the current observational uncertainty if Mercury's inner core is larger than at least 1000 km (Van Hoolst et al., 2012). Gravitational inner core–mantle coupling slightly reduces the mantle libration by up to 20 m, and therefore, the mantle moment of inertia derived from the libration is also somewhat smaller than if derived from eqn [94] (Van Hoolst et al., 2012).

Tides also affect the librations by changing the gravitational torque exerted by the Sun on Mercury and by changing the polar moment of inertia. Their effect on the amplitude of the 88-day forced libration is, however, at most 0.5% (Van Hoolst et al., 2012), corresponding to a difference of below 2 m, which is below the (future) observational precision expected to be about 10 m or somewhat smaller (Pfyffer et al., 2011). The main cause of the difference is the change in the torque (Van Hoolst et al., 2012).

10.04.5.3.2 Free libration

Libration (eqn [85]) averaged over an orbital period governs free libration. The periodic torques with periods equal to the mean motion and its harmonics, the terms on the right-hand side of eqn [85], are therefore not considered for free libration. The total torque of the Sun is, however, not neglected; otherwise, there would not be any libration anymore. The part of the torque that causes free libration is proportional to the libration angle γ (see the second term in the left-hand side of eqn [85]). When the long axis does not point toward the Sun at perihelion ($\gamma \neq 0$), the averaged gravitational torque on the permanent figure of Mercury tends to restore the alignment, and the long axis will librate around the direction to the Sun at perihelion. The oscillation period is given by

$$P_{\text{free}} = \frac{2\pi}{n}\left[\frac{1}{3}\frac{C^{\text{m}}}{B-A}\frac{1}{e\left(\frac{7}{2}-\frac{123}{16}e^2\right)}\right]^{1/2}. \qquad [95]$$

Free libration is also due to the gravitational interaction between the Sun and Mercury, as is forced libration, but the distinctive feature of free libration as opposed to forced libration is that the amplitude and phase of free libration cannot be determined without knowing its excitation and dissipation, as is the case for a free harmonic oscillator. For $B-A=(3.235\pm0.024)\times10^{-5}MR^2$ (Smith et al., 2012) and $C^{\text{m}}/(MR^2)=0.149\pm0.006$ (Margot et al., 2012), the free libration period is 11.4 years. Although the long period makes this effect more difficult to detect in a few orbital periods of Mercury, the expected lifetime of the space missions MESSENGER and BepiColombo, it also causes the free libration to be much more difficult to detect in spin rate measurements, as currently done with Earth-based radar, than in measurements of the rotational phase with camera, altimeter, or gravitational sensors (Yseboodt et al., 2010).

The amplitude of the free libration depends on excitation and damping processes. Free libration will eventually be damped to zero in the absence of excitation. A main source of damping is the tides caused by the Sun. Mercury reacts viscoelastically to forces that tend to deform it, and inevitably, some energy is lost. A further potential source of damping is due to dissipative core–mantle coupling, due to either core viscosity or ohmic dissipation in the core. The timescale for damping of the free libration by viscous core–mantle coupling and tides is on the order of 10^5 years (Peale, 2005). For the same dissipation parameters as used for the damping of the free precession, the viscous core–mantle coupling dominates the tidal damping by one order of magnitude (Peale, 2005). The damping timescales are short compared to the age of the solar system. Without recent excitation, the free libration is therefore expected to be completely damped. Impact excitation is very unlikely since the average time span between impacts of sufficient size is about 10^9 years with current cometary fluxes. A recent impact would have left an impact crater of at least 20 km diameter for the excitation of an observable amplitude of 0.1 arcmin (Peale, 2005).

Librations at periods longer than the orbital period are also induced by planetary perturbations as they change Mercury's orbit (Peale et al., 2007). For example, long-period changes on the order of several years in the semimajor axis of Mercury's orbit caused by the other planets imply a change in the mean motion and cause the long axis of Mercury (see libration angle γ) to be misaligned with respect to the direction to the Sun at pericenter. The solar gravitational torque on Mercury then leads to forced librations at these periods. Several of those long-period librations can have amplitudes above 1 arcsec (Peale et al., 2009; Yseboodt et al., 2010, 2013). The largest long-period libration most likely is caused by Jupiter and has a period of 11.86 years. This forcing period is close to the free libration period of 11.4 years. Although it is, within the current error estimates, not equal to the free period, the near resonance can amplify the libration response of Mercury.

When Mercury has a solid inner core inside an outer liquid core, the free libration period can be considerably lengthened (Dumberry, 2011) to a period of about 17.4 years for solid inner cores almost as large as the total core (Van Hoolst et al., 2012). For small inner cores (radius of less than about 1000 km), this can bring the free mode closer to resonance with the Jupiter-induced long-period libration causing a larger resonant amplification. For larger inner core, the free libration period is far from 11.86 years. An inner core changes the free libration period because the inner core librates in phase with the mantle. In addition to changing the free libration, the existence of a solid inner core also introduces a second free mode in which the mantle and inner core librate out of phase (Dumberry, 2011). This second period is shorter than the period of the first free mode, of the order of several years, and might resonantly enhance other long-period librations (Van Hoolst et al., 2012; Yseboodt et al., 2013). Future observations of one of the free modes or of the amplification of a long-period forced libration can yield constraints on the interior structure of Mercury, including its inner core size.

Besides excitation of long-period libration due to planetary perturbations, decadal libration might also be caused by time-dependent zonal flows generated by turbulent convection in Mercury's fluid outer core (Koning and Dumberry, 2013). Those flows periodically speed up and slow down the inner core through electromagnetic interaction so that also the mantle will start librating as a result of gravitational interaction with the inner core. The libration is largest at forcing periods close to the free libration period at decadal period, and libration amplitudes of the order of 1 arcsec can be reached for zonal flows of the order of 1 km year^{-1} (Koning and Dumberry, 2013). Future observations of decadal libration could be used to constrain the dynamics in the core of Mercury.

10.04.5.4 Wobble

Polar motion of Mercury has never been detected. Due to the very tenuous atmosphere of Mercury, seasonal atmospheric excitation of polar motion as on Earth can be neglected. As for Venus, the CW component of polar motion has a very long period because of Mercury's slow rotation and small flattenings, which are two orders of magnitude larger than the polar rotational flattening. No strong excitation is known at this timescale. Seismic activity is a potential source of CW excitation but is expected to be orders of magnitude smaller than on Earth for the lack of plate tectonics. On the other hand, the dissipation of the CW is less efficient than on Earth due to the slow rotation of Mercury but, for weak excitation, will eventually damp the wobble to very small values.

10.04.6 Summary

The rotation of the four terrestrial planets of our solar system has changed substantially since the planets' formation. The rotation history cannot be uniquely described, but recent advances have led to a deeper understanding of their current rotation state. All four planets could have experienced large chaotic variations in obliquity due to resonances between the precession rate and the orbit precession rate. Their obliquities can therefore not be considered as primordial and almost do not constrain the primordial obliquities. The rotation rates have also been changed. Because Mars is further from the Sun than the other terrestrial planets and has no large satellites, tidal braking has only had a small influence on its spin rate, which can be considered to be primordial. Mercury and Venus are in a stable final rotation state, as a result of dissipative processes. Therefore, their current spin gives little insight into their primordial rotation. Although the occupied final spin states have been shown to be the most probable outcomes of the rotational evolution, the physical dissipation mechanisms are not well constrained and need further study.

Short periodic rotation variations of the Earth have been studied since antiquity and are nowadays routinely tracked with submilliarcsecond accuracy (see **Chapters 3.10** and **3.09**). Theoretical techniques developed for the Earth are now being applied to the other terrestrial planets, but data have so far only been obtained for the largest rotation variation components with limited precision. Seasonal LOD variations on Mars have recently been determined with a precision of about 5% for the largest signal and can be used to constrain GCMs of the Martian atmosphere and the seasonal sublimation/condensation cycle of the polar caps. By using Earth-based radar observations, both the libration and the obliquity of Mercury have recently been measured with an uncertainty of also about 5%. These data prove that the core of Mercury is at least partially liquid and offer unprecedented constraints on the deep interior structure of Mercury.

The next decade promises to be an exciting one for the study of periodic rotations variations of Mars and Mercury. Continued radio-tracking observations of Mars orbiters such as Odyssey and MRO will improve LOD variations and make it possible to resolve the Mars CW period. This will aid in the construction of accurate GCMs and will constrain further the interior of Mars. In addition, in 2016 the NASA Discovery Program mission InSight (Interior Exploration using Seismic Investigations, Geodesy and Heat Transport) will place a geophysical lander on Mars to study its deep interior. The RISE experiment of InSight will use the X-band communications transponder to obtain two-way Doppler and ranging measurements from the radio links resulting in an order of magnitude better accuracies on the rotation, on the order of a few mas. Besides improving LOD variations and polar motion, it will detect the nonrigid contributions to nutations and so offer direct information on the core of Mars. Earth-based radar observations of Mercury and measurements by the MESSENGER and BepiColombo missions to Mercury will improve the libration and obliquity determination to an accuracy of about an arcsec or better. The total planetary moment of inertia and the ratio of mantle to whole planet moment of inertia can then accurately be determined, with expected precisions of about 1%, yielding important information on Mercury's deep interior. Moreover, Venus Express data are expected to continue better constraining the rotation variations induced by the atmosphere.

10.05.1 Introduction

One of the most precise ways to investigate the subsurface structure of a planet is through the analysis of seismic waves. While such endeavors have proved to be remarkably successful for Earth, the emplacement of a geophysical network that includes seismometers on a terrestrial body such as Mercury, Venus, Mars, or the Moon is both costly and technologically challenging (see Chapter 10.03). Fortunately, alternative means exist to probe the interior structure of the terrestrial planets from orbit. One such method, reviewed in Chapter 10.04, is through analyses of a planet's time-variable rotation. By the measurement of precessional and tidal signals, the moment of inertia factor and k_2 Love number can be constrained, from which constraints on the density and viscosity profile can be obtained. The magnetic induction response of a planet to time-variable magnetic fields can be used to determine how the body's electrical conductivity (and hence

 http://dx.doi.org/10.1016/B978-0-444-53802-4.00169-X

composition) varies with depth. Finally, because the gravitational field of a planet is sensitive to its internal density structure, another powerful method that can be used to probe the subsurface, and which is the subject of this review, is the joint analysis of gravitational and topographic data.

The past two decades have witnessed dramatic advancements in our understanding and knowledge of the gravitational fields and topography of the terrestrial planets. These advances are intimately related to the acquisition of radio tracking data from orbiting spacecraft, measurements of the range and range rate between co-orbiting satellites, measurements of gravitational gradients from orbit, the collection of data from orbiting altimeters, and the construction of terrain models from stereo imagery. As examples, from data collected by NASA's Lunar Reconnaissance Orbiter (LRO; Vondrak et al., 2010) and Gravity Recovery and Interior Laboratory (GRAIL) (Zuber et al., 2013a) missions, respectively, launched in 2009 and 2011, the gravity and topography of the Moon are now known better globally than any other planetary object, including Earth. The topography of Venus was mapped by the technique of radar altimetry during the Magellan mission (placed in orbit in 1990; Saunders et al., 1990), and radio tracking data acquired during this mission has led to the construction of a global gravity model. From the laser altimeter onboard the Mars Global Surveyor (MGS) mission (placed in orbit in 1997; Smith et al., 2001a), the topography of Mars has been mapped to high resolution, and radio tracking of this and subsequent spacecraft has allowed for continued improvement to the Martian gravity field. In a similar manner, radio tracking and laser altimetry are being used by the MESSENGER spacecraft that is currently in orbit about Mercury (Solomon et al., 2001). Finally, the topography and gravitational field of Earth are continually being refined, most notably by a series of recent and ongoing missions such as GRACE (Gravity Recovery and Climate Experiment; Tapley et al., 2005) and GOCE (Gravity Field and Steady-State Ocean Circulation Explorer; Drinkwater et al., 2003).

From a geophysical and comparative planetology perspective, the motivation for obtaining high-resolution gravitational and topographic data is to place constraints on the formation, interior structure, and geologic evolution of a planet. The magnitude and direction of the gravitational acceleration exterior to a planet are completely determined by its internal distribution of mass, a result of Newton's law of gravitation. When combined with topographic data and reasonable geologic assumptions, it becomes possible to invert for important geophysical parameters, such as crustal thickness, elastic thickness, and crustal and mantle densities. These model parameters can then be used to address questions concerning planetary differentiation, crust formation, thermal evolution, and magmatic processes. Since the spatial resolving power of gravitational measurements decreases with increasing distance from the object, these investigations are generally restricted to the crust and upper mantle.

Very few research articles have been written that review the gravitational fields and topography of the terrestrial planets from a comparative planetology perspective: useful summaries can be found in Phillips and Lambeck (1980), Balmino (1993), Bills and Lemoine (1995), and Rummel (2005). The purpose of this chapter is both to review the current state of knowledge of the gravitational fields and topography of the terrestrial planets and to review the tools that are used to describe and analyze these data. While gravitational and topographic datasets can each be used independently to make inferences about the interior structure of a planet, such results are often based upon hypotheses that are not easily testable or models that are highly underconstrained. Thus, although regional topographic models have been constructed for some moons and asteroids (such as Phobos (Wählisch et al., 2010), 433 Eros (Gaskell et al., 2008; Zuber et al., 2000a), Itokawa (Abe et al., 2006; Gaskell et al., 2008), Vesta (Jaumann et al., 2012), Ganymede (Giese et al., 1998), Europa (Nimmo et al., 2003a,b; Nimmo et al., 2007), Iapetus (Giese et al., 2008), Mimas (Dermott and Thomas, 1988), Enceladus (Thomas et al., 2007), Tethys (Thomas et al., 2007), Dione (Thomas et al., 2007), Rhea (Thomas et al., 2007), and many of the irregularly shaped satellites of Saturn (Thomas, 2010)) and the longest wavelength gravitational fields and topography have been constrained for others (such as Io (Anderson et al., 2001a; Thomas et al., 1998), Europa (Anderson et al., 1998), Ganymede (Anderson et al., 1996b; Palguta et al., 2006), Callisto (Anderson et al., 2001b), Rhea (Anderson and Schubert, 2010), Titan (Iess et al., 2010; Lorenz et al., 2013), and Vesta (Konopliv et al., 2013a)), this chapter will focus on those planetary bodies for which the gravity and topography are both characterized to high resolution, namely, Earth, Venus, Mars, Mercury, and the Moon.

The outline of this chapter is as follows. First, in **Section 10.05.2**, a general review of the mathematical formalism that is used in describing the properties of gravitational fields and topography is given. In **Section 10.05.3**, the basic properties of the gravitational fields and topography of Earth, Venus, Mars, Mercury, and the Moon are characterized. Following this, **Sections 10.05.4–10.05.7** discuss the relationship between gravity and topography and how the two datasets can be used to invert for geophysical parameters. These methods include crustal thickness modeling, the analysis of geoid/topography ratios (GTRs), modeling of the spectral admittance and correlation functions, and localized spectral analysis and wavelet techniques. **Section 10.05.8** summarizes the major results that have been obtained for these planetary bodies, and **Section 10.05.9** concludes by discussing future developments that can be expected in this domain.

10.05.2 Mathematical Preliminaries

This section reviews the mathematical background that is required to understand how gravitational fields and topography are characterized and manipulated. As most analysis techniques make use of spherical harmonics, the first subsection defines these functions and introduces certain concepts such as the power spectrum. The following subsection gives definitions that are specific to the gravitational potential, gravitational field, and geoid. For further details, the reader is referred to several key books and articles such as **Chapter 3.02**, Jeffreys (1976), Kaula (1967), Kaula (2000), Heiskanen and Moritz (1967), Lambeck (1988), and Hofmann-Wellenhof and Moritz (2006).

10.05.2.1 Spherical Harmonics

Spherical harmonics are the natural set of orthogonal basis functions on the surface of the sphere. As such, any real square-integrable function can be expressed as a linear combination of these as

$$f(\theta, \phi) = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} f_{lm} Y_{lm}(\theta, \phi) \quad [1]$$

where Y_{lm} is the spherical harmonic function of degree l and order m, f_{lm} is the corresponding expansion coefficient, and θ and ϕ represent the position on the sphere in terms of planetocentric colatitude and longitude, respectively. Alternative representations include the use of ellipsoidal harmonics (e.g., Garmier and Barriot, 2001; Jekeli, 1988) when the function is known globally and Slepian functions (Simons et al., 2006) or spherical cap harmonics (e.g., Haines, 1985; Hwang and Chen, 1997; Thébault et al., 2006, 2004) when the function is known only regionally. This chapter will use exclusively planetocentric coordinates, where colatitude is measured with respect to the polar axis, but the reader should be aware that many datasets for Earth make use of planetographic coordinates. Planetographic latitude differs from planetocentric latitude in that it is defined as the angle between the normal to an ellipsoid and the equatorial plane.

In geodesic and gravitational applications, the real spherical harmonics are defined as

$$Y_{lm}(\theta, \phi) = \begin{cases} \overline{P}_{lm}(\cos\theta)\cos m\phi & \text{if } m \geq 0 \\ \overline{P}_{l|m|}(\cos\theta)\sin|m|\phi & \text{if } m < 0 \end{cases} \quad [2]$$

where the normalized associated Legendre functions are given by

$$\overline{P}_{lm}(\mu) = \sqrt{(2-\delta_{0m})(2l+1)\frac{(l-m)!}{(l+m)!}} P_{lm}(\mu) \quad [3]$$

and where δ_{ij} is the Kronecker delta function. The unnormalized Legendre functions in the aforementioned equation are defined in relation to the Legendre polynomials by

$$P_{lm}(\mu) = \left(1-\mu^2\right)^{m/2} \frac{\mathrm{d}^m}{\mathrm{d}\mu^m} P_l(\mu) \quad [4]$$

$$P_l(\mu) = \frac{1}{2^l l!} \frac{\mathrm{d}^l}{\mathrm{d}\mu^l} \left(\mu^2 - 1\right)^l \quad [5]$$

The normalized associated Legendre functions are orthogonal for a given value of m according to

$$\int_{-1}^{1} \overline{P}_{lm}(\mu)\overline{P}_{l'm}(\mu)\mathrm{d}\mu = 2(2-\delta_{0m})\delta_{ll'} \quad [6]$$

and the spherical harmonics are orthogonal over both l and m with the normalization

$$\int_{\Omega} Y_{lm}(\theta, \phi) Y_{l'm'}(\theta, \phi)\mathrm{d}\Omega = 4\pi\delta_{ll'}\delta_{mm'} \quad [7]$$

where $\mathrm{d}\Omega = \sin\theta\ \mathrm{d}\theta\ \mathrm{d}\varphi$. Multiplying eqn [1] by $Y_{l'm'}$ and integrating over all space, the spherical harmonic coefficients of the function f can be obtained from the integral

$$f_{lm} = \frac{1}{4\pi} \int_{\Omega} f(\theta, \phi) Y_{lm}(\theta, \phi)\mathrm{d}\Omega \quad [8]$$

A useful visualization property of the spherical harmonic functions is that they possess $2|m|$ zero crossings in the longitudinal direction and $l-|m|$ zero crossings in the latitudinal direction. In addition, for a given spherical harmonic degree l, the equivalent Cartesian wavelength is $\lambda \approx 2\pi R/\sqrt{l(l+1)}$, where R is the mean planetary radius, a result known as the Jeans relation. It should be noted that those coefficients and spherical harmonics where $m=0$ are referred to as zonal, those with $l=|m|$ are sectoral, and the rest are tesseral. Furthermore, the zonal coefficients C_{l0} are often written as $-J_l$.

Using the orthogonality properties of the spherical harmonic functions, it is straightforward to verify that the total power of a function f is related to its spectral coefficients by a generalization of Parseval's theorem:

$$\frac{1}{4\pi} \int_{\Omega} f^2(\theta, \phi)\mathrm{d}\Omega = \sum_{l=0}^{\infty} S_{ff}(l) \quad [9]$$

where

$$S_{ff}(l) = \sum_{m=-l}^{l} f_{lm}^2 \quad [10]$$

is referred to as the power spectrum of the function. (The term 'power' is here used in the sense of the signal processing literature; namely, the square of the function divided by the area that it spans.) It can be shown that S_{ff} is unmodified by a rotation of the coordinate system. Similarly, the cross power of two functions f and g is given by

$$\frac{1}{4\pi} \int_{\Omega} f(\theta, \phi) g(\theta, \phi)\mathrm{d}\Omega = \sum_{l=0}^{\infty} S_{fg}(l) \quad [11]$$

where

$$S_{fg}(l) = \sum_{m=-l}^{l} f_{lm} g_{lm} \quad [12]$$

is defined as the cross power spectrum. If the functions f and g have a zero mean (i.e., their degree-0 terms are equal to zero), then $S_{ff}(l)$ and $S_{fg}(l)$ represent the contributions to the variance and covariance, respectively, for degree l. Some authors plot routinely the power per degree, $S/(2l+1)$, or the root-mean-square (rms) amplitude of the spherical harmonic coefficients, $\sqrt{S/(2l+1)}$.

One source of confusion with spherical harmonic analyses is that not all authors use the same definitions for the spherical harmonic and Legendre functions. In contrast to the 'geodesy' or '4π' normalization of eqn [7] (cf. Kaula, 2000), the seismology (e.g., Dahlen and Tromp, 1998) and physics (e.g., Varshalovich et al., 1988) communities often use orthonormal harmonics, whose squared integral is equal to unity. The geomagnetic community employs Schmidt seminormalized harmonics whose squared integral is $4\pi/(2l+1)$ (e.g., Blakely, 1995). A more subtle problem is related to a phase factor of $(-1)^m$ (the Condon–Shortley phase) that is sometimes applied to either eqn [3] or [4]. Whereas the spherical harmonics used by the geodesy and geomagnetic communities both exclude this phase factor, those in the physics and seismology communities often include it. To convert the spherical harmonic coefficients from one normalization to another (here labeled by

superscripts 1 and 2), it is necessary only to recognize that the product of the spherical harmonic coefficient and function is independent of the normalization:

$$f_{lm}^{(1)}Y_{lm}^{(1)} = f_{lm}^{(2)}Y_{lm}^{(2)} \qquad [13]$$

In order to obtain the spherical harmonic coefficients f_{lm} of a function f, it is necessary to be able to calculate accurately both the normalized Legendre functions of eqn [3] and the integral of eqn [8]. Methods for efficient calculation of the normalized associated Legendre functions depend upon the use of well-known three-term recursion formulas. If starting values used in the recursion are appropriately scaled, as is summarized by Holmes and Featherstone (2002), these can be computed to high accuracy up to a maximum spherical harmonic degree of about 2700. To obtain a similar accuracy at higher degrees would require the use of an alternative scaling algorithm (e.g., Fukushima, 2011; Jekeli et al., 2007).

The integrals of eqn [8] are most easily performed if the function f is known on a set of evenly spaced grid points in longitude. Numerical methods for calculating this integral involve Fourier transforming each latitudinal band and then integrating over latitude for each l and m (e.g., Sneeuw, 1994). If the function is sampled on an $n \times n$ grid, with n even, and if the function is known to be bandlimited to a maximum degree $n/2-1$, then the spherical harmonic transform can be computed exactly (see Driscoll and Healy, 1994). Alternatively, the integral over latitude can be performed using Gauss–Legendre quadrature (e.g., Press et al., 1992, pp. 140–149). While the integrand of eqn [8] is not in general a terminating polynomial, if the function is bandlimited to a maximum degree n, $n+1$ points in latitude are sufficient to calculate accurately the spherical harmonic expansion coefficients. Publicly available software packages, such as SHTOOLS developed by the author, are readily available for performing the calculations in this manuscript (see **Table 1** for a list of Internet resources).

10.05.2.2 Gravity, Potential, and Geoid

The gravitational acceleration $\mathbf{g}$ at position $\mathbf{r}$ that results from a mass dm at position $\mathbf{r}'$ is given by Newton's law of gravitation:

$$\mathbf{g}(\mathbf{r}) = -G\mathrm{d}m\frac{\mathbf{r}-\mathbf{r}'}{|\mathbf{r}-\mathbf{r}'|^3} \qquad [14]$$

Given that the curl of $\mathbf{g}$ is zero, this vector force field is conservative, and the gravitational acceleration can be expressed as the gradient of a scalar potential U:

$$\mathbf{g}(\mathbf{r}) = \nabla U(\mathbf{r}) \qquad [15]$$

where the gradient operator in spherical coordinates is

$$\nabla = \hat{r}\frac{\partial}{\partial r} + \hat{\theta}\frac{1}{r}\frac{\partial}{\partial \theta} + \hat{\phi}\frac{1}{r\sin\theta}\frac{\partial}{\partial \phi} \qquad [16]$$

The gravitational potential can be calculated at an arbitrary point by a simple integral over the mass distribution

$$U(\mathbf{r}) = \int_V \frac{G\rho(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}\mathrm{d}V' \qquad [17]$$

where ρ is the mass density and V signifies that space occupied by the body. Whereas the sign convention of eqns [15] and [17] are consistent with that used in the geodesy literature, it should be noted that other disciplines, such as physics, place a negative sign in front of each of these equations.

Exterior to the mass distribution V, it can be shown that the potential satisfies Laplace's equation (e.g., Kaula, 2000, chap. 1):

$$\nabla^2 U(\mathbf{r}) = 0 \qquad [18]$$

By using this relationship and the method of separation of variables, the potential U exterior to V can be expressed alternatively as a sum of spherical harmonic functions:

$$U(\mathbf{r}) = \frac{GM}{r}\sum_{l=0}^{\infty}\sum_{m=-l}^{l}\left(\frac{R_0}{r}\right)^l C_{lm}Y_{lm}(\theta,\phi) \qquad [19]$$

Here, the C_{lm}s represent the spherical harmonic coefficients of the gravitational potential at a reference radius R_0, G is the gravitational constant, and M is the total mass of the object. In practice, the infinite sum is truncated beyond a maximum degree L that is justified by the data resolution. The coefficients C_{lm} of eqn [19] are related uniquely to the internal mass distribution of the body, and methods for calculating these

are deferred until Section 10.05.4. Here, it is only noted that the degree-0 coefficient C_{00} is equal to unity and that if the coordinate system has been chosen such that it coincides with the center of mass of the object, the degree-1 terms (C_{10}, C_{11}, and $C_{1,-1}$) are identically zero. The negative order coefficients $C_{l,-m}$ are often referred to as S_{lm}.

As a result of the factor $(R_0/r)^l$ that multiplies each term in eqn [19], the high-frequency components in this sum (i.e., those with large l) will be attenuated when the observation radius r is greater than the reference radius R_0. In contrast, if the coefficients were determined at the altitude of an orbiting satellite, and if this equation were used to determine the potential field on the surface of the planet, then the high-frequency terms would instead be relatively amplified. Since the spherical harmonic coefficients always possess some uncertainty, which generally increases with increasing l, the process of downward continuing a potential field is not stable and must generally be compensated by some form of filtering (e.g., Fedi and Florio, 2002; Phipps Morgan and Blackman, 1993; Wieczorek and Phillips, 1998).

If the body under consideration is rotating, an additional nongravitational force must be taken into account when one is on the surface. In the reference frame of the rotating body, this can be accounted for by adding to eqn [19] a pseudopotential term that is a result of the centrifugal force. This rotational potential, as well as its spherical harmonic expansion, is given by

$$U^{\text{rot}} = \frac{\omega^2 r^2 \sin^2\theta}{2} = \omega^2 r^2 \left(\frac{1}{3} Y_{00} - \frac{1}{3\sqrt{5}} Y_{20} \right) \qquad [20]$$

where ω is the angular velocity of the rotating object. For some applications, especially concerning Earth and Moon, it is necessary to include the tidal potential of the satellite or parent body when calculating the potential (see Dermott, 1979; Zharkov et al., 1985). For a synchronously locked satellite on a circular orbit, the combined tidal and rotational potential in the rotating frame is given approximately by

$$U^{\text{tide+rot}} \simeq \omega^2 r^2 \left(\frac{1}{3} Y_{00} - \frac{5}{6\sqrt{5}} Y_{20} + \frac{1}{4} \sqrt{\frac{12}{5}} Y_{22} \right) \qquad [21]$$

For eccentric and inclined orbits, the reader is referred to Murray and Dermott (2008).

An important quantity in both geodesy and geophysics is the geoid, which is defined to be a surface that possesses a specific value of the potential. (Although one could come up with imaginative names for equipotential surfaces on Mercury, Venus, Eros, Io, and Titan, among others, the term geoid will here be used for all.) As there are no tangential forces on an equipotential surface (see eqn [15]), a static fluid would naturally conform to the geoid. The oceans of Earth are approximately static and are well approximated by such a surface. In geophysics, stresses within the lithosphere are often calculated by referencing the vertical position of a density contrast to an equipotential surface. This is necessary when performing lithospheric flexure calculations, especially when considering the longest wavelengths.

The height N of an equipotential surface above a spherical reference radius R can be obtained by approximating the potential by a Taylor series

$$U(R+N) \simeq U(R) + \frac{\mathrm{d}U(R)}{\mathrm{d}r} N + \frac{1}{2} \frac{\mathrm{d}^2 U(R)}{\mathrm{d}^2 r} N^2 \qquad [22]$$

and setting this expression equal to a constant

$$U(R+N) = \frac{GM}{R} + \frac{\omega^2 R^2}{3} \qquad [23]$$

the value of which is here chosen to be the degree-0 term of the potential at the reference radius R for a rotating planet. Since this equation is quadratic in N, the geoid height can be solved for analytically at any given position. Analytic expressions for the partial derivatives of the potential are obtained easily in the spectral domain from eqns [19] and [20] (see also eqn [25]). It is noted that an analytic expression for the geoid using a third-order expansion of eqn [22] also exists.

For some cases, it is sufficient to use only the first-order term of eqn [22]. If the first derivative of U is approximated by $-GM/R^2$, then the geoid is simply given by

$$N \simeq R \sum_{l=2}^{\infty} \sum_{m=-l}^{l} \left(\frac{R_0}{R} \right)^l C_{lm} Y_{lm} - \frac{\omega^2 R^4}{3\sqrt{5} GM} Y_{20} \qquad [24]$$

where the degree-1 terms have been assumed to be zero. Although the maximum difference between the first- and second-order methods is less than half a meter for the Moon, Mercury, and Venus, differences of up to 26 and 42 m are obtained for Earth and Mars, respectively. The poor performance of the first-order approximation for Earth and Mars is a result of the large rotationally induced flattening of these two planets.

Despite the simplicity of the aforementioned method for obtaining the height to an equipotential surface, the question arises as to *which* equipotential surface should be used. For Earth, a natural choice is the potential corresponding to mean sea level. However, for the other planets, the choice is more arbitrary (but often not important). As the aforementioned equations for calculating the potential are strictly valid only when the observation point is exterior to the body, one manner of picking a specific potential might be to choose that value for which all points on the geoid are exterior to the body. (Calculation of the potential below the surface of a planet would require knowledge of the interior density distribution.) Another approach that could be used would be to use the mean potential on the planet's equator. Alternatively, the geoid could be chosen such that it best fits, in a least squares sense, the observed shape of the planet (Ardalan et al., 2010).

The radial component of the gravitational field is calculated by taking the first radial derivative of eqn [19]. Ignoring the rotational potential, and using the sign convention that gravitational accelerations are positive when directed downward, this is given by the expression

$$g_r = \frac{GM}{r^2} \sum_{l=0}^{\infty} \sum_{m=-l}^{l} \left(\frac{R_0}{r} \right)^l (l+1) C_{lm} Y_{lm} \qquad [25]$$

Note that this equation differs from the potential only by the inclusion of the additional factors $1/r$ and $(l+1)$. The second factor gives a greater importance to the higher-degree terms, and it is for this reason that plots of the potential and geoid appear to be smooth when compared to components of the gravitational field. In terrestrial applications, it is common to calculate the gravitational field on the geoid. By inserting

eqn [24] into eqn [25] and ignoring rotational and higher-order terms, it can be shown that the radial component of the gravitational field on the geoid can be approximated simply by replacing the term $(l+1)$ in eqn [25] by $(l-1)$. If it is necessary to calculate the gravity field on an irregular surface, this can be accomplished by using a Taylor series that makes use of the known field and higher-order derivatives on a spherical interface (Hirt, 2012). The standard unit for quantifying gravitational perturbations is the galileo, where $1\ \text{Gal} = 10^{-2}\ \text{m s}^{-2}$, and when plotting gravitational anomalies in map form, it is conventional to use milligals.

Finally, it will be useful to characterize the relationship between the gravitational field and topography in the spectral domain. For this, let us presume that the radial gravity g_{lm} and topography h_{lm} are related by

$$g_{lm} = Q_{lm} h_{lm} + I_{lm} \quad [26]$$

where Q_{lm} is a linear nonisotropic transfer function and I_{lm} is that portion of the gravitational signal, such as noise, that is not predicted by the model (the topography can often be considered noise-free). If I_{lm} is uncorrelated with the topography, then it is straightforward to show that the expectation of S_{gh} will be unaffected by this signal. (This can be shown by multiplying eqn [26] by h_{lm}, summing over all m, and taking the expectation.) In contrast, the expectation of the gravitational power spectrum will depend upon the magnitude of I_{lm}. In particular, for the case where I_{lm} is a random variable that is independent of the surface topography, the expectation of the observed gravitational power spectrum is simply

$$S_{gg}^{\text{obs}}(l) = S_{gg}(l) + S_{II}(l) \quad [27]$$

where S_{gg} is the power spectrum predicted exclusively by the model Q_{lm} and S_{II} is the expectation of the power spectrum of I_{lm}. Thus, gravitational measurement noise will bias the gravitational power spectrum by an additive constant.

In quantifying the relationship between gravity and topography, it is useful to work with ratios of their cross power spectra. One quantity, referred to as the *admittance*, is defined by the cross power of the two functions divided by the power of the topography (e.g., Dorman and Lewis, 1970):

$$Z(l) = \frac{S_{hg}(l)}{S_{hh}(l)} \quad [28]$$

This function is not biased by the presence of noise, and when the transfer function Q_{lm} is isotropic (i.e., independent of m), it is an unbiased estimate of Q_l. Another ratio that is commonly used and that is dimensionless is the *correlation*:

$$\gamma(l) = \frac{S_{hg}(l)}{\sqrt{S_{hh}(l) S_{gg}(l)}} \quad [29]$$

If the coefficients h_{lm} and g_{lm} possess a zero mean, the aforementioned function is simply the correlation coefficient of the two sets of harmonic coefficients for a given degree l, which is bounded between 1 and -1. Whereas noise will not bias the admittance function, it will bias the degree correlation function toward lower values as a consequence of the gravitational power spectrum in the denominator of this expression. The term *coherence* is usually reserved for the correlation squared, but this definition is not universally followed. Since squaring the correlation discards information (its sign), its use is not advocated here. It is noted that the isotropic version of eqn [26] predicts that the spectral correlation coefficient should always be ± 1. Nevertheless, as discussed in Section 10.05.7, nonisotropic models yield expressions that are degree-dependent. Whereas other ratios of cross power spectra could be constructed, only two will be independent. Since the relationship between gravity and topography is nonlinear (see eqn [33]), in the following section, it will be useful to plot the correlation between the observed gravity and the gravity predicted from surface topography.

10.05.3 The Data

10.05.3.1 Earth

10.05.3.1.1 Topography

Despite the fact that the measurement of the Earth's topography and bathymetry has been the subject of numerous government-supported campaigns, large portions of the Earth's surface, namely, the oceans, remain poorly characterized. Indeed, from a global perspective, it can be said that the shapes of Mars and the Moon are known better than that of the planet we call home. Until recently, even the elevations of the aerial portions of the continents possessed long-wavelength uncertainties, a result of mosaicking numerous elevation models, each with its own reference surface, along artificial political boundaries. While major advances have been made in the past decade toward generating global models, the main deficiency is still the sparse bathymetry of the oceans.

Numerous topographic models of the Earth's landmass have been assembled from various sources over the past few decades, including ETOPO1 (1 arc minute resolution; Amante and Eakins, 2009), GLOBE (30 arc second resolution; Hastings and Dunbar, 1999), and GTOPO30 (detailed documentation for these and all following topography models can be found at the appropriate web addresses listed in Table 1). Currently, the most accurate model of the Earth's landmass comes from radar interferometric data collected by the Shuttle Radar Topography Mission (SRTM). During its 10 days of operation onboard the US space shuttle in year 2000, this mission mapped nearly 80% of the landmass between 60°N and 54°S with a horizontal sampling of 1 arc second (~30 m) and an absolute vertical accuracy better than about 10 m (Rabus et al., 2003; Rodríguez et al., 2005). Because of the 5.6 cm wavelength of the radar, elevations correspond to the top of the canopy when vegetation is present.

The bathymetry of the oceans has been measured from ship surveys using echo sounding for over half a century. Unfortunately, the ship tracks sometimes possess large navigational errors, and large data gaps exist. As reviewed by Marks and Smith (2006), many datasets exist that are based upon these measurements, but each has its own peculiarities. In the absence of additional ship survey data, one method that can be used to improve the bathymetry of the oceans is by combining ship survey data with marine gravity data. As is detailed by Smith and Sandwell (1994, 1997), marine gravitational anomalies (as obtained from altimeter-derived sea surface slopes) are highly correlated with seafloor topography over a restricted wavelength band. By combining predicted topography from

bandpassed gravitational anomalies with the long-wavelength bathymetry from shipboard sounding, it has been possible to obtain near-global 2 arc second resolution estimates of seafloor topography. Nevertheless, it should be emphasized that such data products are indeed estimates and that they may be inappropriate for certain types of geophysical modeling.

Global Earth's topography models that combine oceanic bathymetry and landmass topography include ETOPO1 and SRTM30_PLUS. The latter of these represents a combination of the SRTM 30 arc second data and the Smith and Sandwell (1997)-predicted bathymetry, with gaps filled by GTOPO30 data, among others. Using the SRTM, SRTM30_PLUS, and ETOPO1 datasets, a suite of high-degree spherical harmonic models has been constructed by Hirt et al. (2012) (Earth2012) that include models of planetary shape, relief with respect to the geoid, and rock-equivalent topography. An image of this global topographic model is displayed in **Figure 1**, where the elevations are plotted with respect to the EGM96 geoid, which is a good approximation of mean sea level (see Internet documentation in **Table 1** for precise definitions). To obtain absolute radii of Earth (as is necessary for most methods that calculate gravity from topography), it is necessary to add the elevation of the geoid, which is referenced to the WGS84 ellipsoid, and the shape of the WGS84 ellipsoid itself. The WGS84 ellipsoid is a good representation of the Earth's zonal shape and possesses a 21 km rotationally induced difference in elevation between the equator and polar axis. A summary of fundamental planetary constants is given in **Table 2**.

10.05.3.1.2 Gravity

The gravitational field of Earth has been mapped by several techniques, including analyses of satellite radio tracking data, ranging between co-orbiting spacecraft, measurement of gravitational gradients from orbit, and terrestrial measurement campaigns. Satellite altimetry of the ocean surface provides additional constraints, as geoid slopes are proportional to the gravity field in the spectral domain (see, among others, Hwang and Parsons, 1996; Sandwell and Smith, 1997). The construction of global high-resolution models consists of combining the long-wavelength information from satellite tracking data with the short-wavelength information in the terrestrial and oceanic altimeter surveys. The model EGM96 (Lemoine et al., 1998) has been the standard reference for much of the past decade, and this was recently superseded by the model EGM2008 (Pavlis et al., 2012). EGM2008 is complete to degree and order 2160 and makes use of a global 180 degree and order GRACE-based solution, gravitational anomalies over the ocean derived from satellite altimetry, and terrestrial and airborne gravity data. The EIGEN-6c2 gravity model (Förste et al., 2012), developed to degree and order 1949, is largely consistent with EGM2008 and makes use of GRACE intersatellite ranges, GOCE gravity gradients, LAGEOS satellite laser ranging data, ocean geoid, and terrestrial data.

The analysis of data from the ongoing missions (Challenging Mini-Satellite Payload (CHAMP); launched in 2000; Reigber et al., 2004), GRACE (launched in 2002; Tapley et al., 2004), and GOCE (launched in 2009; Floberghagen et al., 2011; Rummel et al., 2011) is providing highly accurate estimates of the Earth's long-wavelength gravity field (corresponding to spherical harmonic degrees less than about 200; Pail et al., 2011) and time variations in gravity resulting from geologic processes. These satellites all utilize continuous satellite to GPS (global positioning system) tracking data for orbit determination. CHAMP and GOCE are single satellites, but the primary payload of GOCE is a three-axis gravity gradiometer. GRACE consists of two satellites on identical orbits, of which the distance between the two is measured to high accuracy by a microwave communication link. The analyses of data from GRACE have been providing monthly global gravity solutions since 2003, allowing for study of hydrogeologic, postseismic deformation, and postglacial rebound phenomena.

The images of the total gravitational and geoid anomalies, as determined from eqn [25] and the second-order approximation of eqns [22] and [24], are shown in **Figure 1** for the model EMG2008. The total gravitational anomaly is here defined as the total gravitational acceleration on the rotating WGS84 ellipsoid after removal of the predicted 'normal gravity' of a homogeneous ellipsoid (e.g., Hofmann-Wellenhof and Moritz, 2006). Though this terminology is in common usage in the geophysics community, geodesists would call this the total gravity disturbance. (In terrestrial geodesy, the gravitational anomaly is defined as the gravity on the geoid minus the normal gravity on the reference ellipsoid, where the two quantities are calculated at different points in space.) The largest gravitational anomalies are seen to be correlated with topography (such as trenches and seamounts), and the geoid height is found to vary by about 200 m.

10.05.3.1.3 Spectral analysis

Spectral and cross-spectral properties of the shape model Earth2012 RET and the EGM2008 potential are plotted in **Figure 2**. For this shape model, the radius of the ocean floor was increased by 1030/2670 times its depth in order to convert the mass of the overlying sea water into 'rock-equivalent topography.' As demonstrated in the left panel, the power spectrum of the geoid is about five orders of magnitude less than that of the topography, which is a reflection of the low amplitudes of the geoid undulations present in **Figure 1**. The error spectrum of the potential model demonstrates that the coefficients are well determined at low degrees, with relative uncertainties gradually increasing to 100% near degree 1800. As a result of the ~260 km altitude of GOCE and the ~400–500 km altitudes of GRACE and CHAMP, the contribution to the gravitational field from these spacecraft is necessarily limited to degrees less than about 250; the higher-degree terms are constrained almost entirely by surface measurements.

The admittance and correlation spectra between the radial gravity and topography are plotted in the right panel of **Figure 2**. Given that the relationship between gravity and topography is nonlinear, especially at high degrees, the correlation spectrum is here calculated using the spherical harmonic coefficients of the free-air gravity and the gravity predicted from topography. The correlation for many of the lowest degrees is seen to be small and in some cases negative. The correlation increases beyond degree 12 from about 0.7 to attain a nearly constant value close to 0.9 near degree 500. The slight decrease in correlation that is observed beyond degree 1800 is likely a result of the sparse gravity coverage over portions of the oceanic and continental crust. If the correlation were calculated using the observed topography,

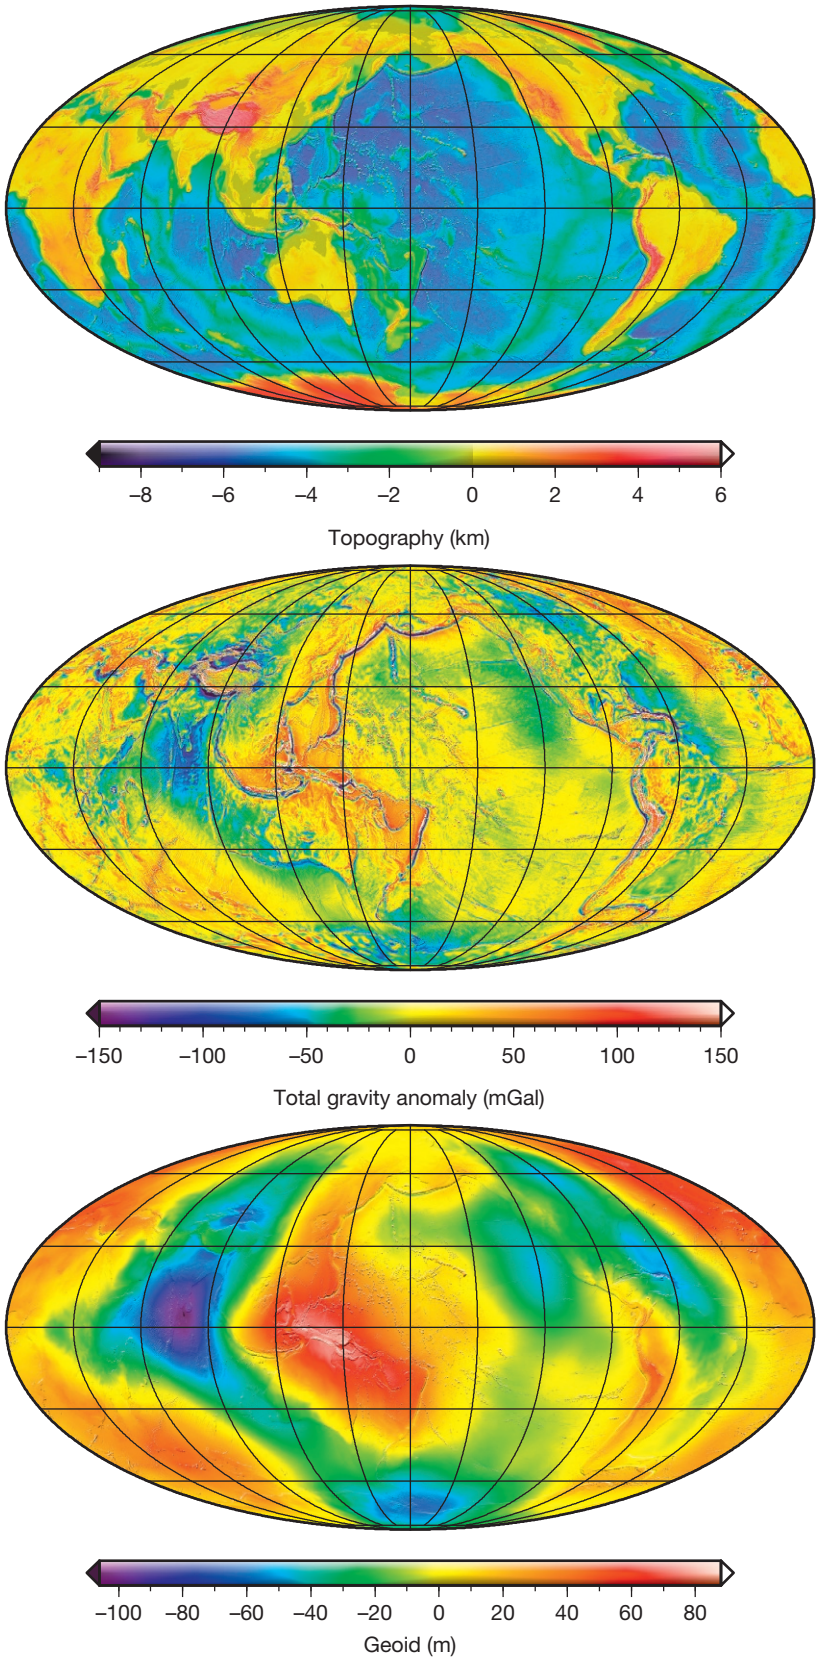

Figure 1 (Top) Global topography and bathymetry of Earth (model Earth2012), referenced to the WGS84 EGM96 geoid, (middle) the EGM2008 total gravitational anomaly on the WGS84 ellipsoid, and (bottom) the height of the EGM2008 geoid above the WGS84 ellipsoid. All images are in a Mollweide projection with a central meridian of 180°W longitude and are overlain by a gradient image derived from the topographic model.

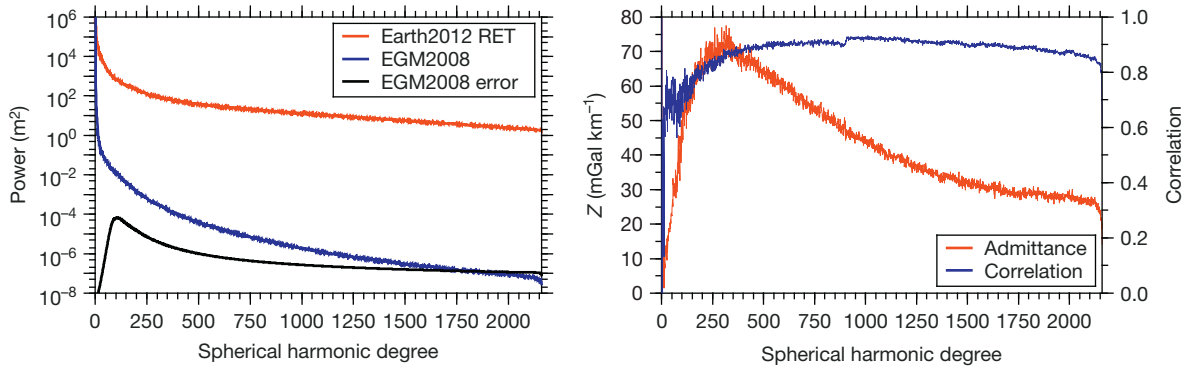

Figure 2 Power and cross power spectra of the Earth's radial gravity and topography. (Left) Power spectra of the topography (Earth2012 RET), geoid (EGM2008), and geoid error. (Right) Admittance and correlation spectra of the radial gravity and topography. The correlation spectrum is calculated using the spherical harmonic coefficients of the observed free-air gravity and gravity predicted from topography.

instead of gravity predicted from topography, the correlation would decrease to less than 0.5 at the highest degrees.

If the surface topography were completely uncompensated, which should be a good approximation beyond degree 300, the admittance would have a near-constant value of $2\pi\rho G$, or 42 mGal km^{-1} times the surface density in units of g cm^{-3}. The observed function is everywhere lower than this theoretical value by about a factor of 2. The low admittances at high degrees are a consequence of the fact that the gravity and surface topography are not perfectly correlated on a global scale as a result of subsurface loads (see discussion in **Section 10.05.6.2**).

10.05.3.2 Venus

10.05.3.2.1 Topography

The planet Venus possesses a dense atmosphere and is perpetually enshrouded by opaque clouds of sulfuric acid. In order to obtain measurements of the surface, it is necessary to make use of electromagnetic frequencies, such as microwaves, where the atmosphere is transparent. Surface elevations of Venus have been measured from orbit using radar altimeters onboard the missions Pioneer Venus Orbiter, Venera 15 and 16, and Magellan. Of these, the Magellan spacecraft, which was in orbit between 1990 and 1994, collected the highest resolution measurements on a near-global scale (for a detailed description, see Ford and Pettengill, 1992).

As a result of the elliptical orbit of the Magellan spacecraft, the spatial resolution of the elevation measurements varied between 8×10 km at periapse and 19×30 km at the north pole (Rappaport et al., 1999). Over 4 million range measurements were ultimately collected, and these were used to construct a 5×5 km gridded elevation model. With the exception of a few relatively minor data gaps covering about 2.6% of the planet's surface area, coverage of the planet is fairly uniform.

(If data from previous missions are used to fill the gaps, then just less than 1% of the planet is not covered at this resolution.) Though the spacecraft-surface range measurements are estimated to have an accuracy of less than 10 m (errors can be larger over rough and steeply sloping terrain), uncertainties in the spacecraft orbit at the time of initial processing were sometimes much greater, especially during superior conjunction. The most recent gravity model of Konopliv et al. (1999) has improved considerably the spacecraft navigational errors, and these improved orbit predictions have been used by Rappaport et al. (1999) in a complete reprocessing of the altimetry dataset (archived as GTDR3.2). Horizontal uncertainties in the footprint locations are insignificant in comparison with the footprint size, and the rms radial uncertainty is estimated to be less than 20 m.

An image of the Venusian topography (derived from the spherical harmonic model VenusTopo719; **Section 10.05.3.2.3**) is shown in **Figure 3**, where it is referenced to the geoid. Whereas the hypsometry of Venus is unimodal (e.g., Ford and Pettengill, 1992; Rosenblatt et al., 1994), in contrast to that of Earth that is bimodal, Venus can be broadly characterized by its low-lying plains, 'continental' plateaus, and volcanic swells. The most prominent highlands include Aphrodite Terra, which lies along the equator, and Ishtar Terra, which is located at high northern latitudes. Ishtar Terra and Aphrodite Terra differ in that the former is flanked by high-elevation mountain ranges. Isolated domical volcanic provinces that possess prominent rift valleys include Atla (0°N, 200°E) and Beta (25°N, 280°E) Regiones. The highest topographic excursion corresponds to Maxwell Montes, located in Ishtar Terra, which reaches more than 10 km above the surrounding plains.

10.05.3.2.2 Gravity

Models of the gravitational field of Venus have been constructed through the analyses of tracking data from the Pioneer Venus Orbiter and Magellan spacecraft (for a review, see Sjogren et al., 1997). The orbit of the Pioneer Venus spacecraft was highly eccentric and possessed periapse altitudes as low as 150 km near the equator. The Magellan spacecraft was initially on an eccentric orbit as well, but through the technique of aerobraking during the gravity mapping phase of the mission, the orbit was transformed to a more circular one, with periapse and apoapse altitudes varying between 155–220 and 350–600 km, respectively.

The most recent model of the Venusian gravitational field is the 180 degree and order JPL (Jet Propulsion Laboratory) model MGNP180U of Konopliv et al. (1999). Because of computational constraints at the time, this model was constructed in three phases. In the first step, a model to spherical harmonic degree 120 was generated using the full unconstrained covariance matrix and a spatial a priori constraint that depended on the strength of the gravitational accelerations (such models are labeled SAAP for Surface Acceleration A Priori). The second step used this model as the nominal solution and then solved for the coefficients from degrees 116 to 155 using the same spatial constraint. For the third step, the coefficients were determined from degrees 154 to 180, but instead of using a spatial constraint, the spherical harmonic coefficients were biased toward a global power law (i.e., a 'Kaula rule'). Future models could be improved by performing the inversion in a single step. As a result of the spatial constraint that was employed in the first two steps, the spatial resolution of the model varies dramatically with position on the surface. Spectral resolutions approaching spherical harmonic degree 180 may be realized close to the equator, but other regions possess resolutions as low as degree 40 (see **Figure 3** of Konopliv et al., 1999).

Images of the MGNP180U radial gravitational field and geoid are presented in **Figure 3**, evaluated at a radius of 6051 km, where the spectral coefficients have been truncated beyond degree 65. As a result of the slow retrograde rotation of Venus, there is no appreciable rotational flattening of the planet. These plots show that most gravitational and geoid anomalies are highly correlated with the surface topography. The largest radial gravitational anomalies are associated with the volcanoes Maat and Ossa Mons in Atla Regio, with values reaching about 270 mGal. The high elevations of Maxwell Montes, Beta Regio, and numerous smaller volcanic provinces are also seen to possess significant anomalies. Uncertainties in the radial component of the gravitational field are typically 10 mGal at the surface but can be as high as 50 mGal in places.

Like Earth, the geoid undulations of Venus possess a dynamic range of only ~200 m. The largest geoid anomalies correspond to the volcanic swells of Atla and Beta Regiones and the continental regions of Aphrodite Terra and Ishtar Terra. It is also seen that the plains with the lowest elevations possess negative geoid anomalies. Uncertainties in the geoid are typically 1 m but can reach values as high as 4 m.

10.05.3.2.3 Spectral analysis

A 719 degree and order spherical harmonic shape model (VenusTopo719) of Venus was constructed by the author based on the Magellan GTDR3.2 sinusoidally projected data product (see **Table 1**). Missing nodes were filled by data obtained by the Pioneer Venus and Venera 15/16 missions; the remaining gaps were filled by interpolation using the Generic Mapping Tools (GMT) (Wessel and Smith, 1991) command <pr>surface</pr> with a tension parameter of 0.35, and the spherical harmonic expansion was performed using the sampling theorem of Driscoll and Healy (1994). The resulting power spectrum was found to be insensitive to changes in the tension parameter, and the mean planetary radius varied by about 1 m among the various models. A comparison between this spherical harmonic model and the one of Rappaport et al. (1999) shows that the latter suffers from an increasing loss of fidelity with increasing degree (the degree correlation between the two models is ~0.93 at 360°).

Power spectra of the Venusian topography (VenusTopo719) and geoid (MGNP180U) are shown in the left panel of **Figure 4**. These are similar to those of Earth, with the exception that the amplitudes of the degree-1 and degree-2 topographic terms for Venus are relatively smaller. On a log–log plot (data not shown), a change in slope of the topographic power spectrum occurs near degree 100 (Rappaport et al., 1999). This feature might be real, but it is also possible that it is related to interpolating over data gaps before performing the spherical harmonic expansion. The error spectrum of the geoid is seen to be greater than the geoid itself for degrees greater than 65. Though the global values of the potential coefficients are generally unreliable beyond this degree, it should be noted that the spatial resolution of the gravitational field is a strong function of position on the surface. Discontinuities in the error spectrum

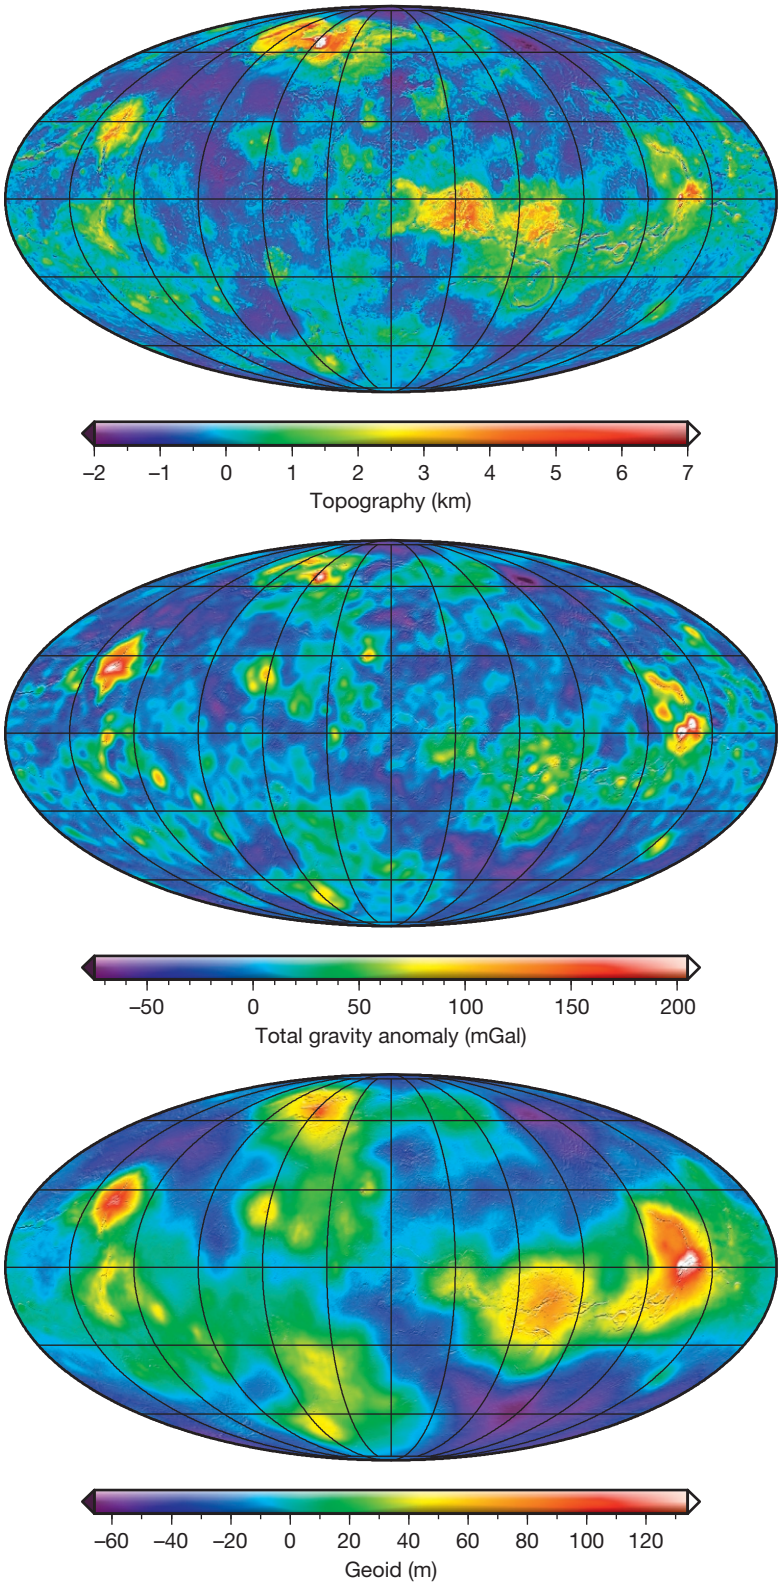

Figure 3 (Top) Global topography of Venus, derived from the spherical harmonic model VenusTopo719, referenced to the geoid. (Middle) Total free-air gravitational anomaly, obtained after truncating the spherical harmonic coefficients of MGNP180U beyond degree 65. (Bottom) Second-order approximation to the geoid. All images are in a Mollweide projection with a central meridian of 60°E longitude and are overlain by a gradient image derived from the topographic model.

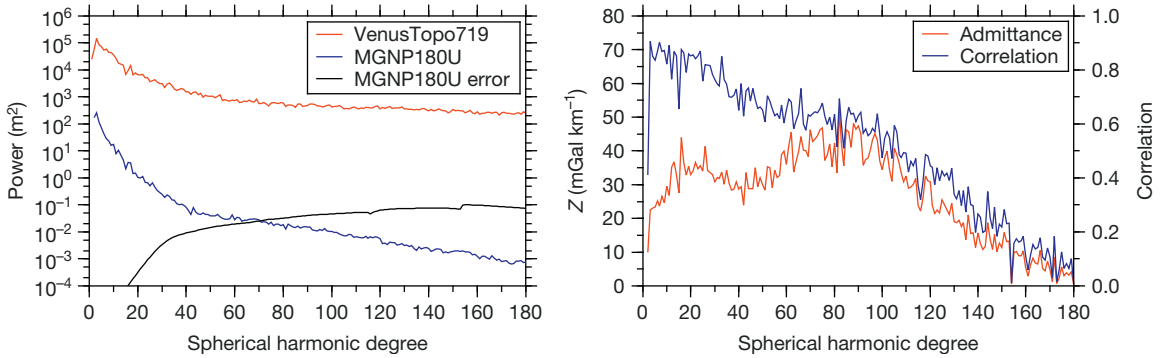

Figure 4 Power and cross power spectra of the gravity and topography of Venus. (Left) Power spectra of the topography (VenusTopo719), geoid (MGNP180U), and geoid error. (Right) Admittance and correlation spectra of the radial gravity and topography. The correlation spectrum is calculated using the spherical harmonic coefficients of the observed free-air gravity and gravity predicted from topography.

are artifacts of solving for the potential coefficients in three separate steps.

The spectral admittance and correlation functions for the radial component of the gravitational field and topography, plotted in the right panel of Figure 4, are seen to differ significantly from those of Earth. The admittance possesses values between ~30 and 50 mGal km^{-1} for spherical harmonic degrees up to 100, whereas for Earth, the admittance linearly increases from ~0 to 70 mGal km^{-1} up to degree 250. The correlation between the gravitational field and topography is also significantly higher for degrees less than 40 than it is for Earth. Nevertheless, beyond about degree 100, the spectral correlation and admittance are seen to decrease linearly with increasing degree, which is a result of the poor determination of the global potential coefficients. It is of note that both the admittance and correlation for degree 2 are significantly smaller than the neighboring values. As these are unaffected by the slow retrograde rotation of the planet, these low values may demand an origin that is distinct from the higher degrees.

Because the Pioneer Venus Orbiter and Magellan spacecraft were in near-polar orbits, the gravity field is better determined for the near-sectoral terms. Sectoral terms correspond to the case $|m|=l$, for which the corresponding spherical harmonic functions do not possess any latitudinal zero crossings. By considering only those coefficients where $l-|m|<20$, Konopliv et al. (1999) had shown that both the admittance and correlation between gravity and topography are considerably greater than when considering all coefficients combined. In particular, the correlation function remains close to 0.7 for degrees up to 140, at which point it decreases substantially. Thus, while high-degree localized spectral analyses may be justified on Venus, the fidelity of the spectral estimates will be a strong function of both position and the spherical harmonic degree and order.

10.05.3.3 Mars

10.05.3.3.1 Topography

Prior to the 1990s, the best Martian topographic models were constructed by a combination of Earth-based radar data, spacecraft radio occultations, and stereo and photoclinometric observations, all of which suffered from either large uncertainties or a limited spatial extent (for a review, see Esposito et al., 1992). The laser altimeter onboard the MGS spacecraft (MOLA, Mars Orbiter Laser Altimeter) has since collected an impressive dataset that has revolutionized studies of the Martian surface (see Smith et al., 2001a, 1999; Zuber et al., 2000b).

MOLA made more than 640 million ranges to the surface over the period of 4 years, after being inserted into orbit in 1997. The spot size of the laser at the surface was ~168 m, and these were spaced every 300 m in the along-track direction of the spacecraft orbit. The intrinsic range resolution of the instrument was 37.5 cm, but range precision decreases with increasing surface slope and could be as poor as 10 m for slopes near 30°. Whereas the along-track orbit errors are less than the size of the laser footprint, radial orbit errors could sometimes be as high as 10 m. Nevertheless, these orbit-induced errors could be minimized by the use of altimetric crossovers. Crossovers occur whenever two altimeter ground tracks intersect, and the difference in the two elevation measurements is largely a reflection of errors in the orbit determination. By parameterizing these uncertainties by a slowly varying function, the crossover residuals can be minimized (Neumann et al., 2001). Such a procedure was capable of reducing the rms crossover residuals from about 8.3 to 1.8 m. Using these methods, it has been possible to measure temporal variations in CO_2 snow depth that can reach 2 m in the polar regions (Smith et al., 2001b).

The topography of Mars (as determined from the 2600-degree spherical harmonic model MarsTopo2600; see in the succeeding text) referenced to the geoid (calculated to second-order accuracy) is displayed in Figure 5. Two of the most remarkable features are the dichotomy in elevation between the Northern and southern hemispheres and the regionally high elevations of the Tharsis volcanic province that is centered near the equator at 100°W longitude. These two features give rise to a 3.3 km offset of the center of figure from the center of mass that is directed toward 64°S and 99°W, of which the longitudinal offset is directed toward the Tharsis province. In addition to these long-wavelength features, there is also an ~20 km difference between the polar and equatorial radii that is a result of the planet's rotational flattening.

Other major topographic features include the giant Hellas (40°S, 65°W), Argyre (50°S, 40°W), and Isidis (15°N, 85°E)

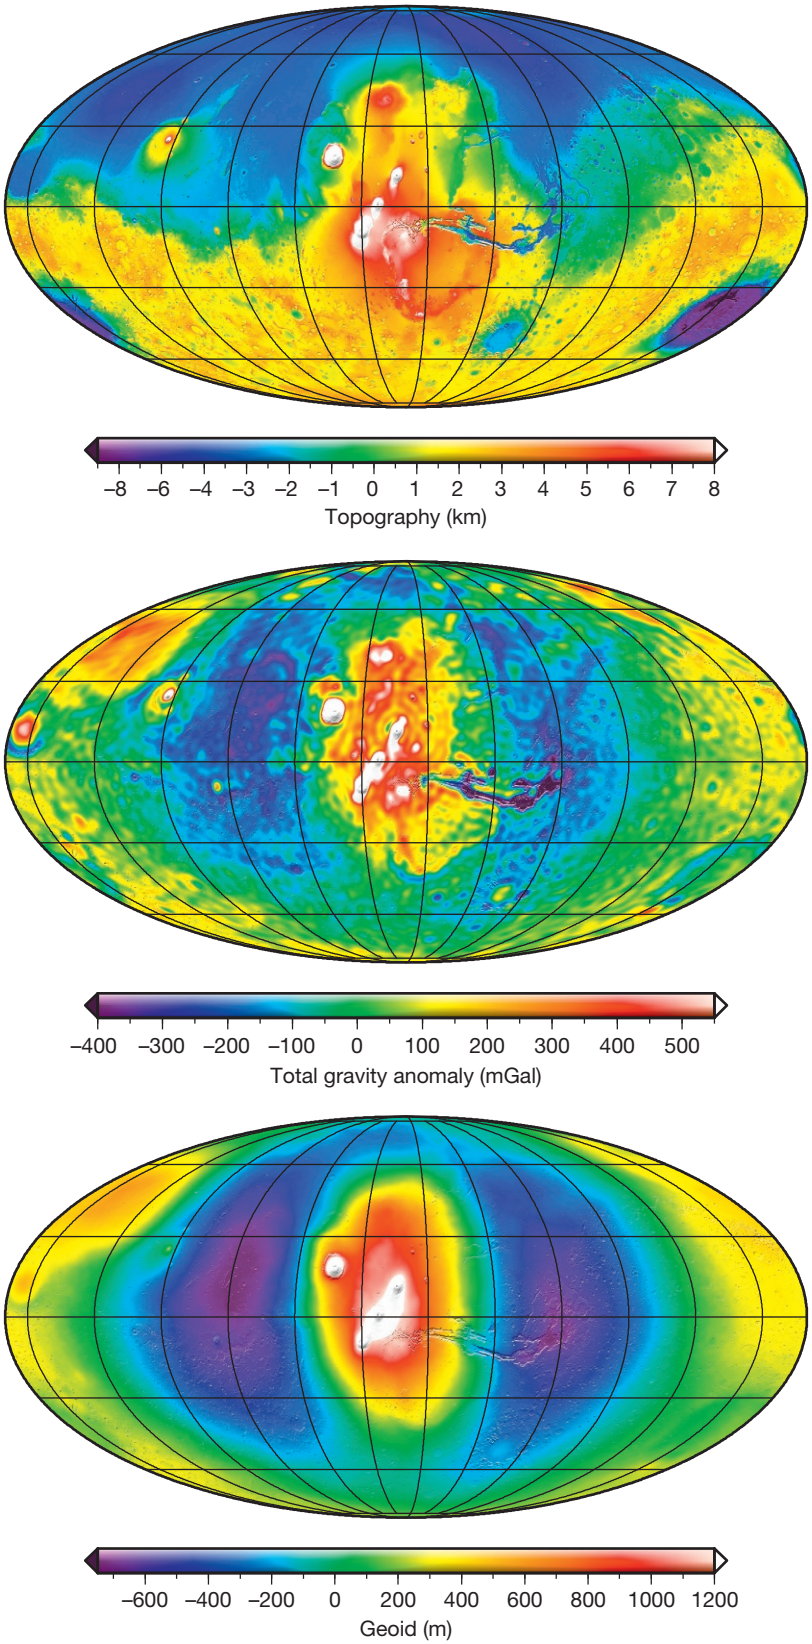

Figure 5 (Top) Global topography of Mars derived from the spherical harmonic shape model MarsTopo2600, referenced to the geoid. (Middle) Total free-air gravitational anomaly on the rotating reference ellipsoid of Ardalan et al. (2010), obtained after truncating the spherical harmonic coefficients of JGMRO_110C beyond degree 85. (Bottom) Second-order approximation to the geoid height with respect to the reference ellipsoid. All images are in a Mollweide projection with a central meridian of 100°W longitude and are overlain by a gradient image derived from the topography model.

impact basins; the Elysium volcanic province (25°N, 145°E); the rift valley Valles Marineris; and the prominent volcanoes that are superposed on the Tharsis province. The highest elevation corresponds to the volcano Olympus Mons, which rises almost 22 km above the MOLA reference geoid.

10.05.3.3.2 Gravity

The gravitational field of Mars has been improved by the successive acquisition of radio tracking data from the Mariner 9, Viking 1 and 2, MGS, Mars Odyssey, and Mars Reconnaissance Orbiter (MRO) missions. A major improvement in the gravity solutions came with the acquisition of data from the MGS mission (see Konopliv et al., 2006; Lemoine et al., 2001; Yuan et al., 2001). This spacecraft was in a near-polar orbit, and during the early portion of the mission when the orbit was highly elliptical, tracking data from altitudes as low as 170 km were acquired at latitudes between 60° and 85°N. Through the technique of aerobraking, the spacecraft was put into a near-circular mapping orbit with periapse and apoapse altitudes of 370 and 435 km, respectively. Mars Odyssey acquired some tracking data from altitudes as low as ~200 km (primarily over the southern hemisphere), with the rest from a near-circular 390 × 455 km mapping orbit. The last major advance was the collection of tracking data from the MRO spacecraft. For this mission, tracking data were acquired from an elliptical orbit with periapse altitudes as low as 255 km over the south pole and apoapse altitudes of 320 km over the north pole. Data were also collected for a brief period with altitudes as low as 220 km over the northern hemisphere.

The most recent and highest resolution gravity solution of Mars is the JPL 110 degree and order model JGMRO_110C (Konopliv et al., 2011). This model employs MGS, Mars Odyssey, and MRO tracking data in combination with surface tracking data from the Pathfinder lander, the latter of which were used to improve knowledge of the orientation of Mars. In the absence of a priori constraints, inversions for the global spherical harmonic coefficients give rise to an unrealistic power spectrum beyond degree 85. In order to obtain a higher-resolution model with realistic power, a Kaula constraint was applied beyond this degree. This solution also obtained the seasonal even zonal J_2 and the better determined odd zonal J_3 signals that result from CO_2 mass exchange between the two polar ice caps and the k_2 Love number from time-variable signals associated with tides raises by the Sun.

An image of the total gravitational anomaly of the model JGMRO_110C is plotted in Figure 5, where the spherical harmonic coefficients have been truncated beyond degree 85. For this map, the normal gravity field predicted for the Mars rotating reference ellipsoid of Ardalan et al. (2010) was removed. Clearly visible are the large positive anomalies associated with the volcanoes in the Tharsis plateau and a negative gravity moat that surrounds this province (Phillips et al., 2001). Large positive anomalies are also evident for some of the largest impact basins, such as Isidis, Argyre, and the buried Utopia basins (45°N, 110°E) that lie in the northern plains. A negative gravitational anomaly is clearly associated with the Valles Marineris rift valley, and negative anomalies surrounding some mountains and volcanoes seem to indicate a flexural origin. The spatial resolution of this field varies laterally, with an effective resolution near spherical harmonic degree 86 for northern latitudes and 110 near the south pole. Formal uncertainties in the radial gravity are at most 10 mGal (A. Konopliv, personal communication).

The Martian geoid, as obtained from the model JGMRO_110C and plotted with respect to the reference ellipsoid of Ardalan et al. (2010), is shown in Figure 5. The geoid undulations of Mars are seen to possess the largest amplitudes among the terrestrial planets, with a dynamic range of over 2.5 km. The signal is largely symmetrical about the Tharsis province, where a central geoid high is surrounded by an annular low. Other geoid highs are associated with the Isidis and Utopia impact basins, as well as the Elysium volcanic rise. Uncertainties in the geoid are generally no more than 2 m (A. Konopliv, personal communication).

10.05.3.3.3 Spectral analysis

The power spectra of the Martian topography (from the author's spherical harmonic model MarsTopo2600, calculated from the gridded datasets available at the PDS (planetary data system) website) and geoid (JGMRO_110C), are plotted in Figure 6. In comparison with the topographic power spectrum, the Martian geoid is seen to have greater amplitudes by about two orders of magnitude than both Earth and Venus. Furthermore, the first 5 degrees of the Martian geoid is considerably greater than would be expected based upon an

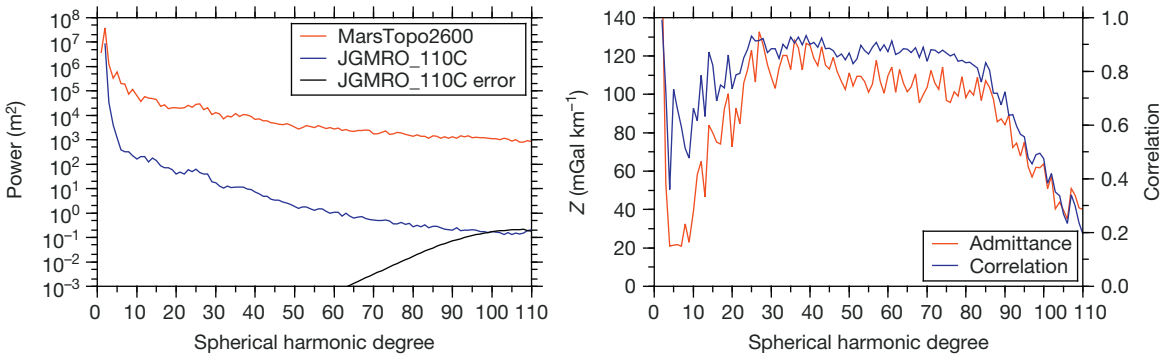

Figure 6 Power and cross power spectra of the gravity and topography of Mars. (Left) Power spectra of the topography (MarsTopo2600), geoid (JGMRO_110C), and geoid error. (Right) Admittance and correlation spectra of the radial gravity and topography. The correlation spectrum is calculated using the spherical harmonic coefficients of the observed free-air gravity and gravity predicted from topography.

extrapolation of the higher-degree terms. This low-degree signal is likely a consequence of the lithospheric load and deflection associated with the Tharsis province (see Phillips et al., 2001; Zuber and Smith, 1997). The error spectrum of the geoid is seen to be larger than the signal for degrees greater than ~100.

The admittance and correlation of the radial gravitational field and topography are shown in the right panel of Figure 6. The admittance function gradually increases with increasing degree, attaining a relatively constant value beyond degree 30. Beyond degree 85, both the admittance and correlation decrease as a result of the poor resolution of the gravity field. While the shape of the admittance function is somewhat similar to that of Earth, it is important to note that the amplitudes are considerably larger at high degrees (~100 mGal km^{-1} in comparison with ~35 mGal km^{-1}). Indeed, these large values are comparable to what would be expected for uncompensated surface topography. One apparent anomaly with the admittance spectrum is the relatively high value of 53 mGal km^{-1} for the degree-three term.

With few exceptions, the correlation between the gravity and gravity predicted from topography is also seen to be very high, with values between about 0.8 and 0.9. Similar to the Venusian gravity model, the near-sectoral terms of the Martian gravity solutions are relatively better determined because of the near-polar orbits of the MGS and MRO spacecraft. When only these near-sectoral terms are used ($l - |m| < 10$), the correlation between the gravity and topography is considerably larger than that shown in Figure 6 for degrees greater than 85 (Konopliv et al., 2011).

10.05.3.4 Mercury

10.05.3.4.1 Topography

Prior to the MErcury Surface, Space ENvironment, GEochemistry, and Ranging mission, MESSENGER (Solomon et al., 2001), the shape of Mercury was only poorly constrained by Earth-based radar ranging to equatorial latitudes (Anderson et al., 1996a; Clark et al., 1988; Harmon et al., 1986) and by a few local elevations models made from Mariner 10 stereo imagery (André et al., 2005). MESSENGER has since acquired a wealth of topographic data by means of satellite laser altimetry (Smith et al., 2010c; Zuber et al., 2008, 2012), stereophotogrammetry (Preusker et al., 2011), optical limb measurements (Oberst et al., 2011), and spacecraft radio occultations (Perry et al., 2011). The spacecraft continues to acquire data in an extended mission.

MESSENGER was launched in 2004, performed three flybys of Mercury in 2008–09, and was placed into a near-polar orbit in 2011. The orbit of the spacecraft during the mapping phase was highly elliptical, with altitudes varying from about 200 km at latitudes near 60°N to about 15 200 km over the southern hemisphere. Because of this, the laser altimeter could range southward only to 15°S. The laser spot size on the surface varied with altitude, from about 15 to 100 m, and the laser shots were separated by about 400 m along track. The near-polar orbit led to dense altimetric coverage near the north pole, decreasing coverage toward the equator. Supplementing these measurements, ~180 radio occultation point measurements of the planet's shape were made when the spacecraft passed behind the planet, with about half of these being located in the southern hemisphere. The processing of stereo imagery has led to the construction of a global elevation model, and a future challenge is to combine the stereo-derived shape models with the laser altimetry and radio occultation data.

The global shape of Mercury derived from stereo imaging (R. Gaskell, personal communication) is shown in Figure 7. As expected from images of the surface, the planet has been shaped largely by impact processes. Several large impact basins, such as the 1500 km diameter Caloris basin (31°N, 160°E), are visible as are numerous smaller craters. The largest basins are not as topographically distinct as those on Mars and the Moon, suggesting that post-basin modification processes have operated after their formation. One clear example of this is the topographic bulge in the northern portion of the Caloris impact basin that is higher than most of its topographic rim (Zuber et al., 2012). Smooth plains are also present, particular at latitudes poleward of about 60°N, that are likely to represent volcanic flows (Zuber et al., 2012). In terms of the planet's long-wavelength shape, the highest elevations are found approximately near 0° and 180° longitude, which corresponds to the axis of the planet's minimum principal moment of inertia (e.g., Davies and Batson, 1975).

10.05.3.4.2 Gravity

The gravity field of Mercury has been constrained by radio tracking of the Mariner 10 and MESSENGER spacecraft. Tracking data from Mariner 10 were acquired only during two flybys, and these allowed for an estimation of the degree-2 gravity coefficients J_2 and C_{22} (Anderson et al., 1987). Radio tracking of the MESSENGER spacecraft has since given rise to a dramatic improvement in our understanding of Mercury's gravity field, with global solutions being developed to spherical harmonic degree and order 20 (Genova et al., 2013; Smith et al., 2012). Nevertheless, as a result of the highly eccentric orbit of the spacecraft, the global models are poorly constrained over the southern hemisphere. Whereas errors in the surface gravity field are less than 20 mGals at latitudes poleward of 30°N, errors are more than 60 mGals at latitudes southward of about 30°S (Genova et al., 2013). Gravity models with higher spatial resolution over the northern hemisphere should be possible by using localized inversion approaches (cf. Han et al., 2009) or with a spatially varying constraint as was done for Venus (Konopliv et al., 1999).

The total gravitational anomaly of the model GGMES_20v04 is plotted in Figure 7, where several positive gravitational anomalies are visible with values approaching 180 mGal. Some of these anomalies are associated with clear topographic signatures, such as the Caloris impact basin and a domical rise in the northern lowlands (Smith et al., 2012), whereas others appear to have little correlation with topography. The volcanic northern lowlands (north of about 60°N) are associated with a regional negative gravitational anomaly, as are the low elevations associated with the large Rachmaninoff impact basin (28°N, 56°E). Large regions of high-standing topography do not possess any significant gravitational anomaly, indicating that they are likely to be isostatically compensated.

The height of the geoid of Mercury, measured with respect to the mean planetary radius, has a dynamic range of about 400 m. As seen in Figure 7, the planet has prominent signals

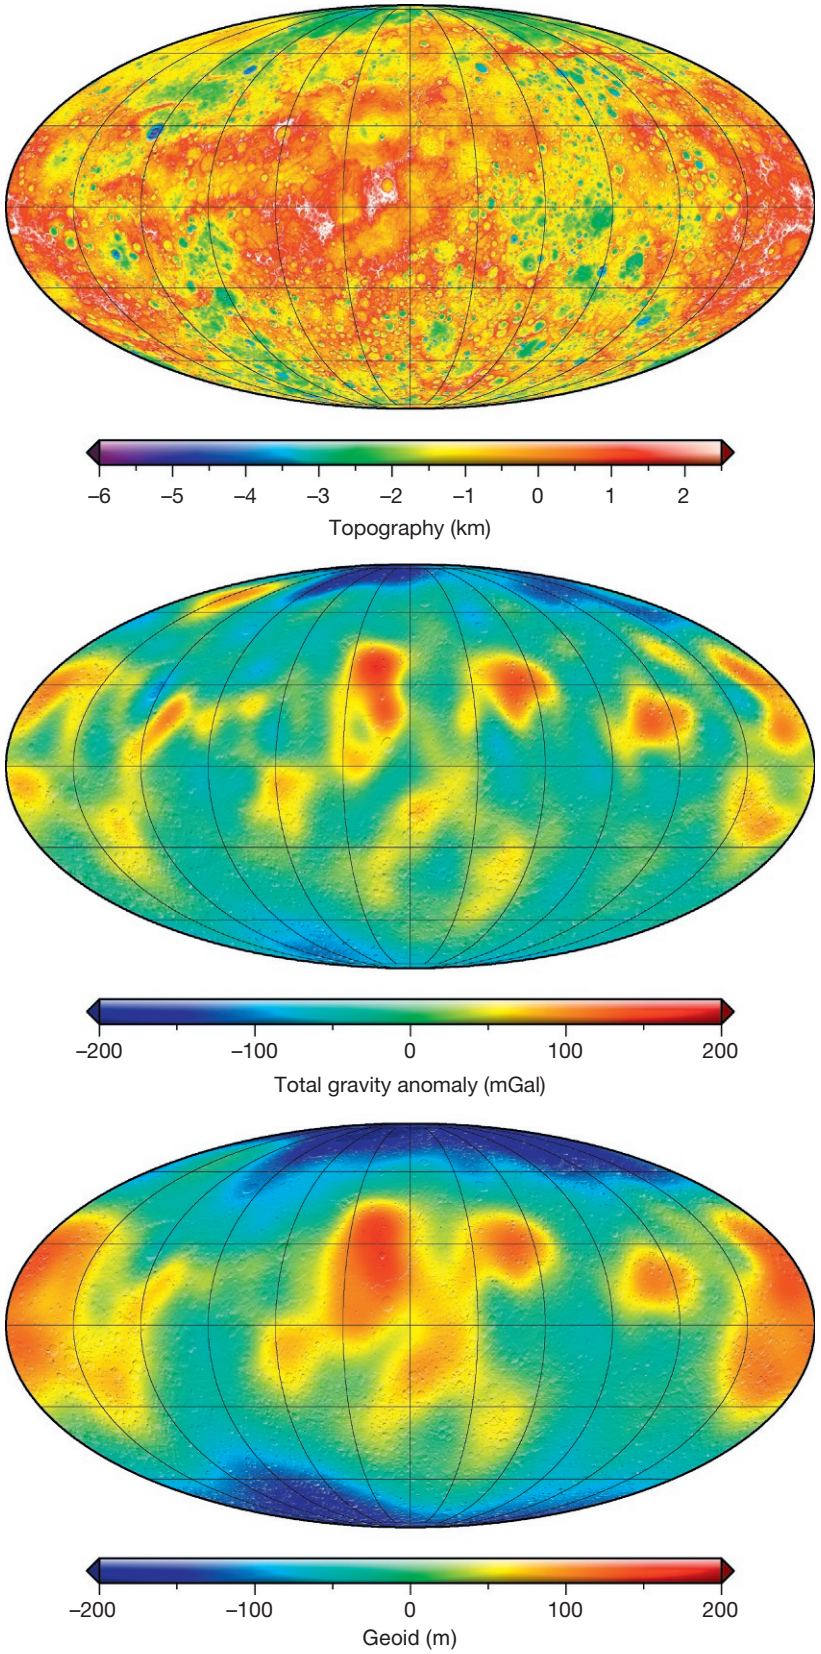

Figure 7 (Top) Global topography of Mercury (R. Gaskell, personal communication), referenced to the geoid. (Middle) Total free-air gravitational anomaly from the spherical harmonic model GGMES_20v04. (Bottom) Second-order approximation to the geoid. All images are in a Mollweide projection with a central meridian of 180°E longitude and are overlain by a gradient image derived from the topographic model.

that arise from the J_2 and C_{22} gravity coefficients. This corresponds to positive geoid anomalies located near 0° and 180° longitude and negative anomalies near both poles, reminiscent of that of the Moon. The C_{22} coefficient is proportional to the difference in the intermediate and minimum principal moments of inertia (e.g., Lambeck, 1988) and is responsible for Mercury having been captured in its present 3/2 spin–orbit resonance (cf. Correia and Laskar, 2009).

10.05.3.4.3 Spectral analysis

A spherical harmonic model of the shape of Mercury was constructed from the MESSENGER laser altimeter and radio occultation data (GTMES_24v01; Smith et al., 2012). The power spectra of this model, the geoid from the model GGMES_20v04, and the geoid error are plotted in **Figure 8**, and the relative amplitudes of the topography and geoid spectra are seen to be comparable to those of Mars. As the error spectrum of the geoid does not intersect that of the geoid, it should be possible to construct higher-resolution models over the northern hemisphere.

The correlation and admittance spectra of the gravitational field and topography are shown in the right panel of **Figure 8**. In this plot, the correlation spectrum was calculated using the observed free-air gravity and the gravity predicted from the surface topography. With the exception of degree 4, the admittance possesses values of a few tens of mGal km^{-1}. This is much less than the value predicted for uncompensated surface topography, indicating that much of the topography at these wavelengths is probably compensated. The correlation possesses values between about 0.4 and 0.8, which is somewhat similar to Mars and the Moon over the same wavelength range. The less than unit correlation is likely a consequence of the presence of mascon basins, such as Caloris, where the gravity and topography are locally anticorrelated, as well as the presence of gravitational anomalies from the mantle and deep crust that do not correlate with surface topography.

10.05.3.5 The Moon

10.05.3.5.1 Topography

The topography of the Moon has been measured by several means, including satellite altimetry, stereophotogrammetry, and radar interferometry (see Wieczorek et al., 2006, for an historical review). However, because of the Moon's synchronous rotation, most early studies were restricted either to the nearside hemisphere or along the equatorial ground tracks of the Apollo command and service modules. The Clementine mission, launched in 1994, was the first to measure absolute elevations of the lunar surface on a near-global scale (Smith et al., 1997; Zuber et al., 1994). 72 548 valid altimetric ranges were acquired along north–south profiles equatorward of ~80°, and in combination with elevation models of the polar regions based on stereophotogrammetry, a global shape model was created (U.S. Geological Survey, 2002). The next major advance came from laser altimetric ranging from three orbiting spacecraft: Kaguya (Araki et al., 2009) and Chang'e 1 (Ping et al., 2009), both launched in 2007, and LRO launched in 2009 (Smith et al., 2010a,b). In addition to including laser altimeters, the acquisition of stereo imagery from these missions has led to the construction of both regional and global terrane models (e.g., Haruyama et al., 2008; Scholten et al., 2012).

The most successful of the recent lunar altimeters is the Lunar Orbiter Laser Altimeter (LOLA) (Smith et al., 2010a,b) onboard the LRO mission. LOLA is a multibeam laser altimeter that operates by spitting a single laser pulse into five output pulses. A five-spot cross pattern is formed on the surface by constructive interference in the far field, which is then detected by five individual receivers, each with a range accuracy of about 10 cm. The spot size of each laser on the surface is 5 m, and the distance between spots is 25 m. The orbital motion of the spacecraft, combined with the 28 Hz repetition frequency, ensures that each five-spot pattern is repeated every 50 m. Bidirectional surface slopes can be calculated for each laser shot or for a variety of longer baselines (Rosenburg et al., 2011). At the present time, more than 6 billion valid ranges have been made to the Moon, and an additional 2 billion are expected over the lifetime of the laser. Since the orbit of the Lunar Reconnaissance Orbiter is polar, the altimetric coverage near the poles is extremely dense. Nevertheless, some kilometer-scale data gaps exist at equatorial latitudes. Stereo imagery can be used to create elevation models with resolutions approaching about 10 m (Haruyama et al., 2008) to 75 m (Scholten et al., 2012), and a future challenge is to combine the altimetric and stereo-based elevation models.

It should be noted that there are two reference frames that are in common use for the Moon (Archinal et al., 2011a,b).

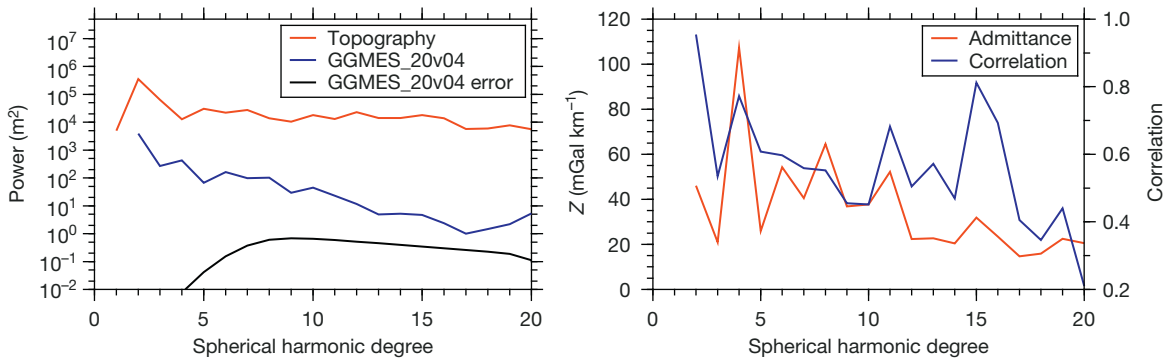

Figure 8 Power and cross power spectra of the gravity and topography of Mercury. (Left) Power spectra of the topography (GTMES_24v01), geoid (GGMES_20v04), and geoid error. (Right) Admittance and correlation spectra of the radial gravity and topography. The correlation spectrum is calculated using the spherical harmonic coefficients of the observed free-air gravity and gravity predicted from topography.

One corresponds to the principal axes defined by the moments of inertia, which is used in the construction of gravitational models. The other is defined by the mean position of Earth and the Moon's rotation axis and is used for many topographic models. The two coordinate frames are mostly offset by a bias with maximum differences up to 873 m, which turns out to be significant when analyzing the high-resolution GRAIL gravity data (Williams et al., 2013). The LOLA topography model (using principal-axis coordinates) is presented in Figure 9 where it is referenced to the GRAIL geoid.

The most dramatic feature of the Moon's topography is the giant South Pole–Aitken impact basin on the farside southern hemisphere. This impact basin possesses a total relief of more than 10 km, and with a diameter of over 2000 km, it is the largest recognized impact structure in the solar system. Other impact basins and craters of various sizes are seen to have shaped the relief of the lunar surface, and the extensive mare basaltic lava flows on the nearside hemisphere, which are relatively younger, are seen to be comparatively smooth. Also of note is that the Moon possesses a 1.9 km displacement of its center of figure from its center of mass in the direction of 8°N and 157°W (e.g., Smith et al., 1997). The total dynamic range in lunar elevation is just under 20 km.

10.05.3.5.2 Gravity

The gravitational field of the Moon has been determined by the radio tracking of orbiting spacecraft and by intersatellite ranging between co-orbiting spacecraft. Radio tracking data from the Lunar Orbiter, Apollo, Clementine, and Lunar Prospector missions led to the development of a degree-150 spherical harmonic model (Konopliv et al., 2001). However, even though the nearside field was moderately well resolved by the 30 km altitude Lunar Prospector data, little was known about the farside hemisphere as it is not possible to track a satellite when it is occulted by the Moon. The first direct tracking data over the farside hemisphere came from the Kaguya mission that was launched in 2007. In addition to the main orbiter (with an altitude of about 100 km), this mission had a relay satellite for performing four-way radio tracking of the main satellite over the farside hemisphere and a subsatellite for very long baseline interferometry (Araki et al., 2009; Goossens et al., 2011; Matsumoto et al., 2010). Data from the Kaguya mission provided a gravitational model that was valid globally to about spherical harmonic degree 70.

The last major advance came with the launch of the GRAIL mission in 2011 (Zuber et al., 2013a,b). This mission was very similar to the terrestrial mission GRACE, in that intersatellite ranges between two co-orbiting spacecraft were used to construct a global gravity model. During the 3 months of the primary mission, the two spacecraft had a mean altitude near 50 km, allowing for the construction of models up to spherical harmonic degree 660 (Konopliv et al., 2013b; Lemoine et al., 2013). During the 3 months extended mission, the altitudes of the two spacecraft were reduced to about 25 km, allowing for the construction of models up to spherical harmonic degree 900. Since the satellite orbits were somewhat elliptical, the minimum elevations over the lunar surface range from only a few kilometers to about 30 km. Though the final models are valid globally to about spherical harmonic degree 750, it is possible to perform localized analyses to higher resolutions where the spacecraft elevations were low.

The total gravitational anomaly and geoid of the GRAIL extended mission model GRGM900B (truncated at degree 550) are plotted in Figure 9. The major features of this map include the large positive gravitational anomalies associated with the nearside impact basins, colloquially referred to as 'mascons' (e.g., Muller and Sjogren, 1968), and the negative gravity moats that surround these basins. The majority of the gravity signal is a result of the surface relief of the Moon, but important signals that are uncorrelated with topography are observed in the lunar mare and elsewhere.

In contrast to Earth, which possesses maximum geoid undulations of ± 100 m, the dynamic range of the lunar geoid is more than 1.1 km. When considering phenomena such as basalt flow directions, it is thus necessary to use elevations that are referenced to the geoid. A long-wavelength J_2 and C_{22} signal is evident in Figure 9, with maxima at the sub- and anti-Earth points, and this signal may represent a fossil tidal deformation that was frozen into the lithosphere early in the orbital evolution of the Moon (e.g., Garrick-Bethell et al., 2006; Jeffreys, 1976; Lambeck and Pullan, 1980).

Finally, it is noted that the orientation of the Moon depends upon its three principal moments of inertia, which are related to the degree-2 gravity coefficients (e.g., Lambeck, 1988). For a synchronously rotating satellite with zero orbital inclination and eccentricity, the minimum energy configuration is achieved when the maximum moment of inertia lies along the rotation axis and when the minimum moment coincides with the Earth–Moon direction (see also Peale, 1969; Ward, 1975). A 180° rotation of the Moon about its rotation axis, as might occur following a large impact event (Wieczorek and Le Feuvre, 2009), would thus be equally stable as its current configuration.

10.05.3.5.3 Spectral analysis

The power spectra of the LOLA principal-axis referenced topography (from the author's model LOLA2600p) and the GRAIL GRGM900B geoid are plotted in the left panel of Figure 10. In comparison with Earth, the power spectrum of the lunar geoid is seen to be about two orders of magnitude more important when compared to the topography spectrum. The lunar geoid and error spectra intersect near degree 750, which is the effective global resolution of the model. Nevertheless, since the GRAIL spacecraft possessed altitudes varying from a few to 30 km during the extended mission, the spatial resolution of the model is in some places better or worse than this spherical harmonic degree. The small upturn in the geoid spectrum near degree 850 is a result of higher-degree aliases that are not resolved by the degree-900 model, indicating that it will be possible to construct even higher-resolution models.

The correlation and admittance spectra for the gravity and topography are plotted in the right pane of Figure 10. In this plot, the correlation spectrum was calculated using the observed free-air gravity and the gravity predicted from the surface topography. The correlation and admittance spectra show low values at the lowest degrees (less than about 0.5 and 100 mGal km^{-1}, respectively). Indeed, these spectra possess negative values for some degrees, indicating that gravity

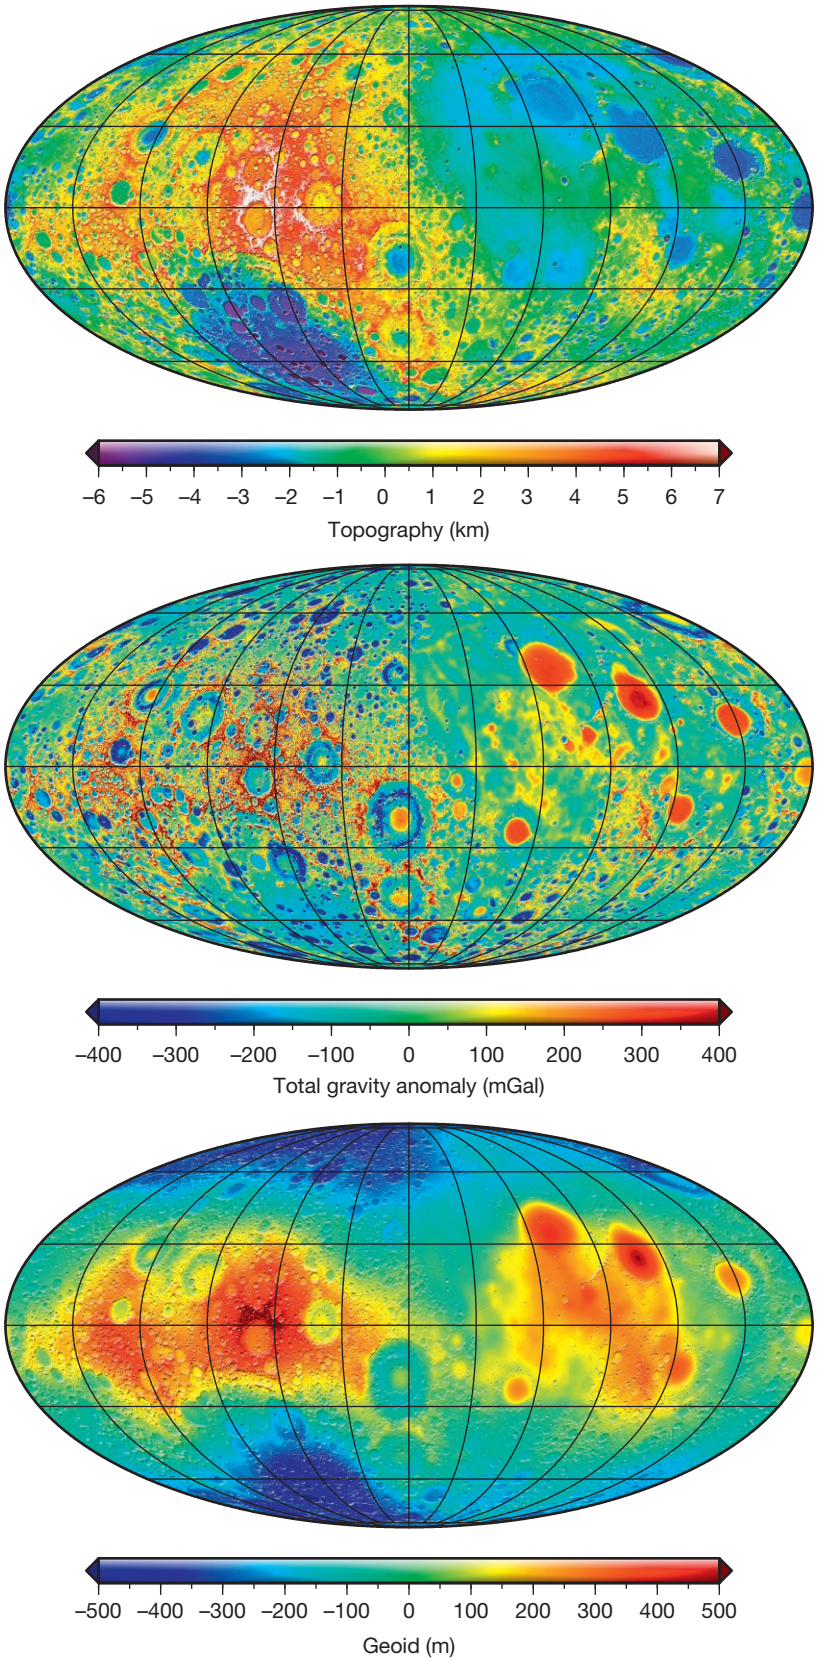

Figure 9 (Top) Global topography of the Moon from the spherical harmonic model LOLA2600p, referenced to the GRGM900B geoid. (Middle) Total gravity obtained from the model GRGM900B evaluated at mean planetary radius after truncating the coefficients beyond degree 550. (Bottom) Second-order approximation to the geoid. All images are in a Mollweide projection with a central meridian of 90°W longitude and are overlain by a gradient image derived from the topographic model. The near- and farside hemispheres are on the right and left halves of these images, respectively.

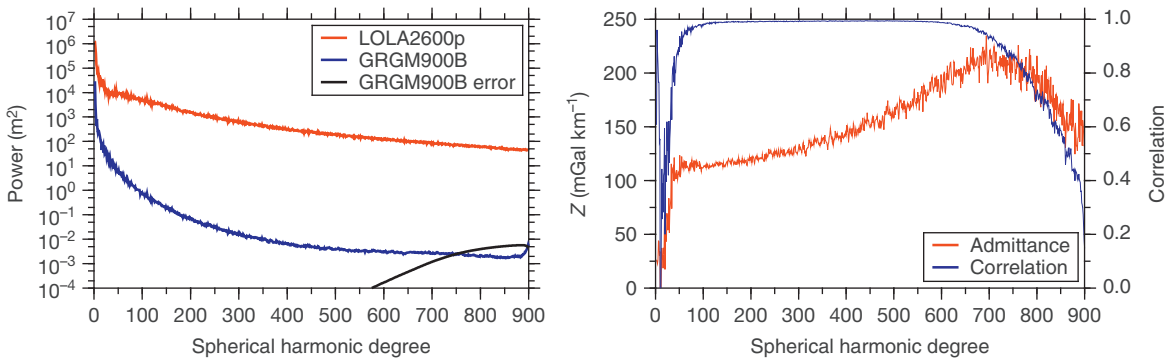

Figure 10 Power and cross power spectra of the gravity and topography of the Moon. (Left) Power spectra of the topography (LOLA2600p), geoid (GRGM900B), and geoid error. (Right) Admittance and correlation spectra of the radial gravity and topography. The correlation spectrum is calculated using the spherical harmonic coefficients of the observed free-air gravity and gravity predicted from topography.

and topography are anticorrelated at these wavelengths. These small values for the lowest degrees are simply a result of the presence of mascon impact basins, which are positive gravitational anomalies that possess low elevations. Beyond about degree 100, the correlation approaches 0.99, and the admittance slowly increases from values near 100 to about 200 mGal km^{-1}. The value of the admittance at these degrees is consistent with uncompensated topography (Wieczorek et al., 2013), and the slow increase in the admittance function is a result of the nonlinear relation between gravity and topography (see **Section 10.05.4**). The correlation starts to decrease near degree 550, and this could be a result of a reduced global fidelity of the gravity model at these degrees or to short-wavelength geologic signals where the gravity and topography signals are not perfectly correlated.

10.05.4 Methods for Calculating Gravity from Topography

Geophysical investigations that employ gravitational and topographic data often attempt to fit the observations with those predicted from a model that contains several parameters. For example, lithospheric flexure calculations depend upon several unknowns, including the effective elastic thickness of the lithosphere, crustal thickness, and the density of the crust and mantle. By comparing predicted gravitational anomalies induced by the deflection of density interfaces with the observed values, the parameters of such a model can be constrained. Whereas several methods exist for calculating the gravitational field related to relief along a density interface, as is described in the succeeding text, this is oftentimes most easily performed in the spherical harmonic domain.

The calculation of the gravitational potential can be considerably simplified by use of the two well-known identities:

$$\frac{1}{|\mathbf{r}-\mathbf{r}'|}=\frac{1}{r}\sum_{l=0}^{\infty}\left(\frac{r'}{r}\right)^{l}P_l(\cos\gamma)\quad \text{for}\, r\geq r' \qquad [30]$$

and

$$P_l(\cos\gamma)=\frac{1}{2l+1}\sum_{m=-l}^{l}Y_{lm}(\theta,\phi)Y_{lm}(\theta',\phi') \qquad [31]$$

where P_l is an unnormalized Legendre polynomial and γ is the angle subtended between $\mathbf{r}$ and $\mathbf{r}'$. (Equation [31] is commonly referred to as the Legendre addition theorem.) By inserting these equations into the expression for the gravitational potential (eqn [17]), it is simple to show that the spherical harmonic coefficients of eqn [19] (the *Stokes coefficients*) are equal to

$$C_{lm}=\frac{1}{MR_0^l(2l+1)}\int_V \rho(\mathbf{r}')r'^l Y_{lm}(\theta',\phi')\mathrm{d}V' \qquad [32]$$

It is important to note that this formulation of the gravitational potential can only be used when the observation point is greater than the maximum radius of the body.

Next, consider the case where there is relief $h(\theta, \phi)$ referenced to a spherical interface of radius D and where the density ρ between h and D depends only on latitude and longitude (when h is negative, ρ is considered negative as well). For this situation, it is possible to obtain exact expressions for the corresponding potential coefficients that are similar to those developed by Parker (1972) in the Cartesian domain. Integrating eqn [32] over r' and expanding powers of the relief in a Taylor series, the potential coefficients of eqn [19], referenced to a radius D, are (see Wieczorek and Phillips, 1998)

$$C_{lm}=\frac{4\pi D^3}{M(2l+1)}\sum_{n=1}^{l+3}\frac{(\rho h^n)_{lm}}{D^n n!}\frac{\prod_{j=1}^{n}(l+4-j)}{(l+3)} \qquad [33]$$

The spherical harmonic coefficients of the density multiplied by the relief to the nth power have the explicit expression (cf. eqn [8])

$$(\rho h^n)_{lm}=\frac{1}{4\pi}\int_\Omega[\rho(\theta,\phi)h^n(\theta,\phi)]Y_{lm}(\theta,\phi)\mathrm{d}\Omega \qquad [34]$$

and when the density is constant, eqn [33] reduces to eqn [9] of Wieczorek and Phillips (1998). As a result of the inequality in the identity of eqn [30], this expression for the potential is valid only when the radius r is greater than the maximum elevation of $D+h$. Extensions, special cases, and alternative forms of this equation have been derived independently several times in the literature (e.g., Balmino, 1994; Chambat and Valette, 2005; Chao and Rubincam, 1989; Martinec et al., 1989; Rapp, 1989). It is worth emphasizing that the relief h in eqn [33] must be calculated with respect to a spherical interface and not the ellipsoid or geoid: using a different reference surface would give inaccurate results.

For the case where the density ρ is constant, the potential coefficients can be obtained simply by calculating the spherical harmonic coefficients of the relief to the nth power. While the sum of eqn [33] is finite and hence exact, the number of terms grows linearly with spherical harmonic degree. Nevertheless, as each succeeding term is smaller than the previous, in practice, this sum can be truncated beyond a maximum value n_{max} for which the truncated terms are smaller than the resolution of the gravity model.

For certain applications, it is sufficient to use the first-order term of eqn [33]:

$$C_{lm} = \frac{4\pi D^2 (\rho h)_{lm}}{M(2l+1)} \qquad [35]$$

This expression is commonly referred to as the 'mass-sheet' approximation, as the calculated gravitational anomaly would be exact if it arose from a spherical interface with a surface density of ρh. (The higher-order terms are referred to as the 'finite-amplitude' or 'terrain' correction.) Using this expression, the radial gravity (see eqn [25]) is seen to approach asymptotically with increasing l the Bouguer slab approximation of $2\pi\rho Gh$.

The effect of truncating the sum of eqn [33] beyond n_{max} is illustrated in Figure 11 for the specific case of determining the Bouguer correction of Earth, Venus, Mars, Mercury, and the Moon. The term Bouguer correction here refers to the contribution of the gravitational potential that results from the mass between the mean planetary radius and the surface. The true value of the Bouguer correction was approximated using $n_{max} = 20$, and the maximum difference of the total gravity in the space domain that results from truncating at lower values of n was calculated on the planet's reference ellipsoid. For these calculations, the full resolution of the planetary topography was used in calculating the potential coefficients, but the resulting gravity field was expanded in the space domain only up to the spherical harmonic degree indicated in the figure. To mitigate against aliases that could arise when raising a function to the nth power, all calculations were performed on a grid that could resolve spherical harmonics up to degree 5000.

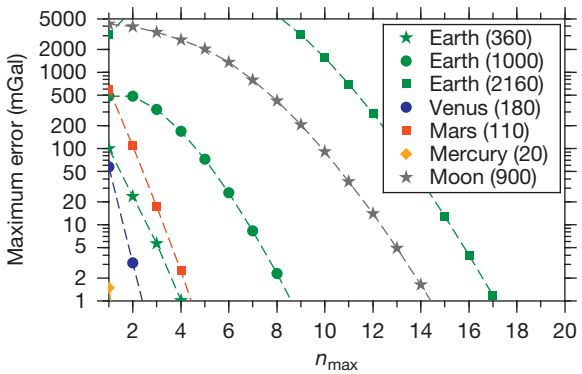

Figure 11 Maximum error associated with the Bouguer correction as a function of the order n_{max}. The Bouguer correction error is here defined as the error in the total gravitational attraction resulting from surface relief with respect to the mean planetary radius, evaluated on the reference ellipsoid. The true value was approximated by $n_{max} = 20$, and the crustal density was assumed to be 2900 kg m^{-3}. The values in parentheses correspond to the maximum spherical harmonic degree used in calculating the gravity field.

Figure 11 shows that the value of n_{max} required to achieve 1 mGal accuracy is highly dependent upon the maximum spherical harmonic degree of the desired gravitational field. To obtain accuracies of a few milligals for Mercury, Venus, and Mars, whose gravity fields are only resolved up to a maximum spherical harmonic degree of 180, only the first four terms of eqn [33] are required. However, when calculating high-resolution gravity fields for the Moon and Earth (with degrees up to 900 and 2160), it is necessary to utilize terms up to 14 and 17, respectively (see also Balmino et al., 2012). If it were necessary to calculate fields up to only spherical harmonic degree 360 for Earth (for use with the gravity model EGM96), then the first four terms would be sufficient.

Finally, it is noted that alternative means exist for calculating the theoretical gravitational field of a body and that these may be preferable to the aforementioned approach for certain applications. One method developed by Belleguic et al. (2005) is quasi-analytic and allows for the calculation of the potential and gravity at any point in a body (this is in contrast to the aforementioned approach that is applicable only to radii greater than the maximum radius). This method starts by mapping irregularly shaped density interfaces to spherical ones and then determines the radial derivatives of the potential and gravitational field on this surface. Using exact values for the potential and gravity field on an interface exterior to the planet (as obtained from a method similar to eqn [33]), these fields are then propagated downward using a first-order Taylor series approximation. This technique is useful for lithospheric flexure calculations as the net lithospheric load is a function of the potential at the major density interfaces.

A second method for calculating the gravitational field is based upon approximating the shape of a celestial body by a polyhedron. Exact expressions for the potential of a homogeneous polyhedron have been derived by Werner and Scheeres (1997), and expressions for the corresponding spherical harmonic coefficients are given in Werner (1997) (see also Tsoulis et al., 2009). The benefit of using this approach is that the resolution of the model (i.e., the spacing between vertices) can be varied according to the resolution of the gravitational field. An application of this method for determining the interior density of an asteroid is given by Scheeres et al. (2000). Alternatively, one could transform eqn [17] into a surface integral by use of Gauss' law and perform the integral numerically for a given shape model (e.g., Cheng et al., 2002).

10.05.5 Crustal Thickness Modeling

It is well known that the modeling of potential fields is nonunique. As an example, eqns [19] and [35] show that any external gravitational field can be interpreted as a surface density ρh placed at an arbitrary radius D. Nevertheless, by using simplifying assumptions based on geologic expectations, it becomes possible to invert uniquely for parameters related to the interior structure of a planet.

Perhaps the simplest example of such an investigation is the construction of a global crustal thickness model. In this case, the nonuniqueness associated with potential modeling is removed by assuming that the observed gravitational field arises only from relief along the surface and crust–mantle

interface and that the densities of the crust and mantle are known. It is further required either to assume a mean crustal thickness or to anchor the inverted crustal thickness to a given value at a specific locale. If lateral density variations in either layer could be constrained by other means, these could be incorporated into the model.

The first step is to calculate the Bouguer correction, which is the contribution to the potential of surface relief referenced to the mean planetary radius. Subtracting this from the observed gravitational field yields the Bouguer anomaly, and this is then ascribed to being caused by relief along the crust–mantle interface at an average radius D. To the first order, this relief could be determined in the spectral domain by downward continuing the Bouguer anomaly coefficients C_{lm}^{BA} to radius D and then setting these equal to those predicted from the mass-sheet approximation of eqn [35]. However, two additional factors generally need to be taken into account in such an analysis. First, downward continuing the Bouguer anomaly amplifies short-wavelength noise that is often present in the observed gravitational field. Second, the first-order mass-sheet approximation may not be sufficiently accurate if the undulations along the crust–mantle interface are large.

By minimizing the difference in the spectral domain between the observed and predicted Bouguer anomalies, the shape of the crust–mantle interface can be computed via the following equation (see Wieczorek and Phillips, 1998):

$$h_{lm} = w_l \left[\frac{C_{lm}^{BA} M (2l+1)}{4\pi \Delta \rho D^2} \left(\frac{R}{D} \right)^l - D \sum_{n=2}^{l+3} \frac{(h^n)_{lm}}{D^n n!} \frac{\prod_{j=1}^{n} (l+4-j)}{(l+3)} \right] \quad [36]$$

The density jump across the crust and mantle is given by $\Delta\rho$, R is the reference radius of the Bouguer anomaly coefficients, and w_l is a filter that stabilizes the downward continuation procedure. The explicit form of the filter can be determined by using an additional constraint that minimizes the mantle relief.

While there is no simple analytic solution to eqn [36], the relief h can be determined using an iterative approach: First, the coefficients h_{lm} are approximated by ignoring the higher-order terms on the right-hand side; then, using this estimate, the higher-order terms are calculated, and a new estimate of h_{lm} is obtained (see also Wieczorek et al., 2013). The second step is iterated until the relief converges to a stable solution. It is important to note that these models do not assume the crust to be isostatically compensated; such a hypothesis could be tested for a given model. Example crustal thickness models that were obtained using this procedure are discussed in the succeeding text, along with the major modeling assumptions that are specific to each body.

Crustal thickness models for Venus and Mars are presented in Figure 12. For the Venusian model, a mean crustal thickness of 35 km was assumed, the potential and topography coefficients were truncated beyond degree 60, and densities of 2900 and 3330 kg m^{-3} were used for the crust and mantle, respectively. The inclusion of finite-amplitude corrections for Venus affects the obtained crustal thicknesses by only a few kilometers. (For alternative models, see Orth and Solomatov, 2012; James et al., 2013.) The model for Mars is an updated version from Neumann et al. (2004) that uses the JGM95J01 gravity model. An average crustal density of 2900 kg m^{-3} was assumed for this model, and the low density of the polar caps, the higher than average densities of the Tharsis volcanoes, and the gravitational attraction resulting from the core flattening were explicitly taken into account. A mean crustal thickness of 45 km was assumed, and in downward continuing the Bouguer anomaly, a filter was constructed such that the power spectrum of the Moho relief resembled that of the surface relief.

A crustal thickness model for Mercury is presented in Figure 13. For this model, densities of 2900 and 3200 kg m^{-3} were used for the crust and mantle, respectively, and the filter w_l was chosen to possess a value of 0.5 at degree 40. Under the assumption that the minimum crustal thickness on Mercury is 5 km, the average crustal thickness is found to be 23 km. Since the spatial resolution of the gravity field is poor in the southern hemisphere, the inverted crustal structure there should be treated with caution. The crustal thickness model for the Moon in this figure is an updated version from Wieczorek et al. (2013) that uses gravity data derived from the GRAIL extended mission. Lateral variations in crustal density, which were estimated from remote sensing data, were used in calculating the gravity field for this model. A crustal porosity of 12% was assumed, a mantle density of 3220 kg m^{-3} was used, and the filter w_l was chosen to have a value of 0.5 at 80°. With an average crustal thickness of 34 km, this model possesses minimum crustal thicknesses that are less than 1 km and fits the 30 km seismic constraint (Lognonné et al., 2003) at the Apollo 12 and 14 landing sites. Neglecting the finite-amplitude terms in eqn [36] would give rise to errors as large as 20 km for the Moon (Neumann et al., 1996).

10.05.6 Admittance Modeling

In the crustal thickness modeling of the preceding section, the nonuniqueness associated with potential modeling was removed by making certain assumptions about the mean crustal thickness and the density of the crust and mantle. These and other parameters can be estimated if one instead assumes that surface topography is supported by a specific mechanism, such as lithospheric flexure or Airy compensation. Using such a model, the relationship between gravity and topography can be determined, and by comparing to the observed values, model parameters can be estimated. As is described in the following two subsections, two methods are in common use: One is based upon modeling the GTR in the space domain, whereas the other models the admittance and correlation functions in the spectral domain.

10.05.6.1 Spatial Domain

One method that has proven to be fruitful for estimating the mean crustal thickness of a planet is modeling of the GTR in the space domain. This technique was initially developed by Ockendon and Turcotte (1977) and Haxby and Turcotte (1978) for Earth, where it was shown that the isostatic geoid anomaly was approximately equal to the vertical dipole moment of density variations within the lithosphere. For the specific cases of Airy and Pratt isostasy, the ratio between the geoid and topography was found to be proportional to

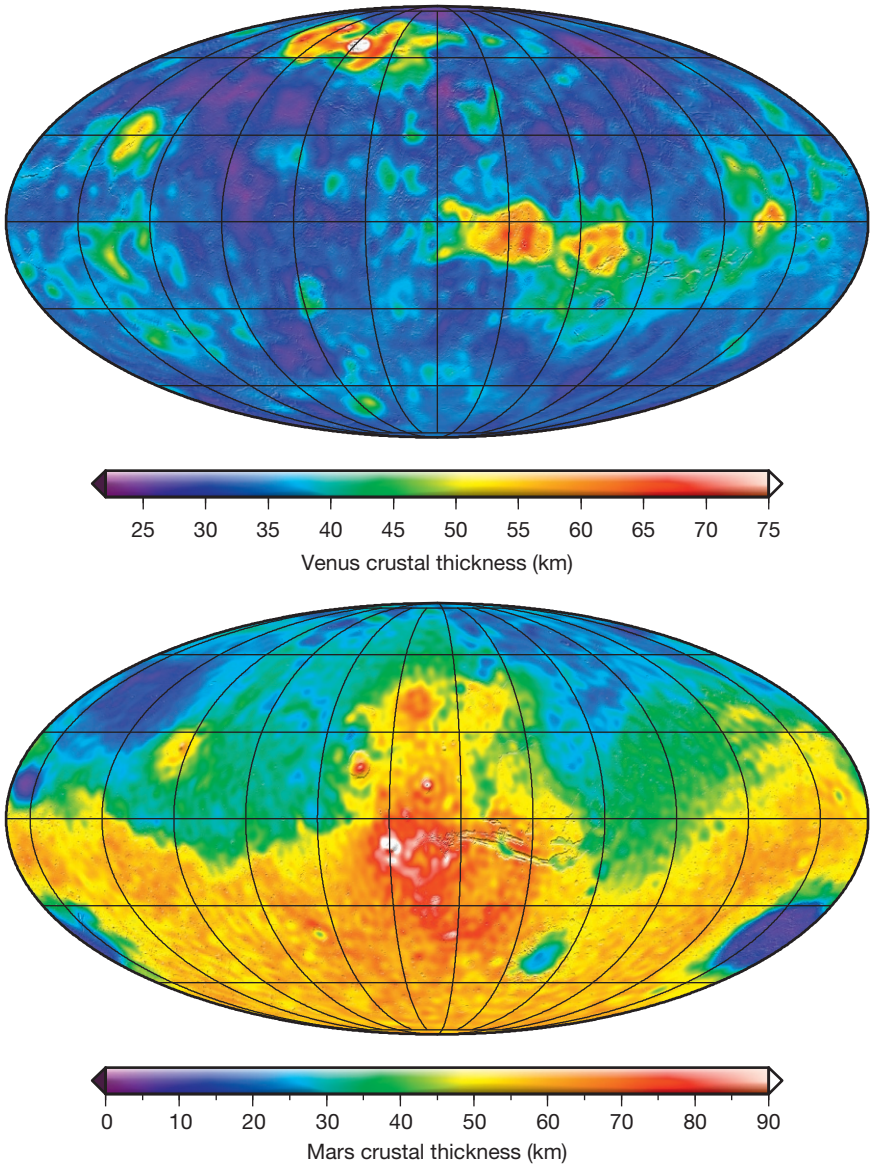

Figure 12 Crustal thickness models for Venus and Mars. Both images are in a Mollweide projection and are overlain by a gradient image derived from the surface topography. The central meridian is 60°E for Venus and 100°W for Mars.

the crustal thickness. Their method was derived using a Cartesian geometry and is strictly valid in the long-wavelength limit.

An alternative approach has been developed in spherical coordinates by Wieczorek and Phillips (1997) where it has been shown that the GTR, N/h, can be approximated by the expression

$$\frac{N}{h} = R \sum_{l=l_{\min}}^{l_{\max}} W_l Q_l \qquad [37]$$

where $l_{\min}$ and $l_{\max}$ correspond to the minimum and maximum spherical harmonic degrees that are considered, R is the mean planetary radius, Q_l is the linear transfer function between the potential and topographic coefficients, and W_l is a weighting function that is proportional to the topographic power of degree l:

$$W_l = S_{hh}(l) \Big/ \sum_{i=l_{\min}}^{l_{\max}} S_{hh}(i) \qquad [38]$$

The underlying assumption of this model is that the GTR is independent of position for a given compensation model, and this has been validated empirically for the highlands of the Moon and Mars for the case of Airy isostasy (Wieczorek and Phillips, 1997; Wieczorek and Zuber, 2004).

As the power spectra of planetary topography are 'red' (i.e., they possess more power at long wavelengths than short wavelengths), eqn [38] shows that the largest contribution to the GTR will come inevitably from the lowest degrees. As an example, approximately 80% of the GTR for the Moon is determined by degrees less than 30. Since the topography of the ancient highland crust of a planet is likely to be isostatically

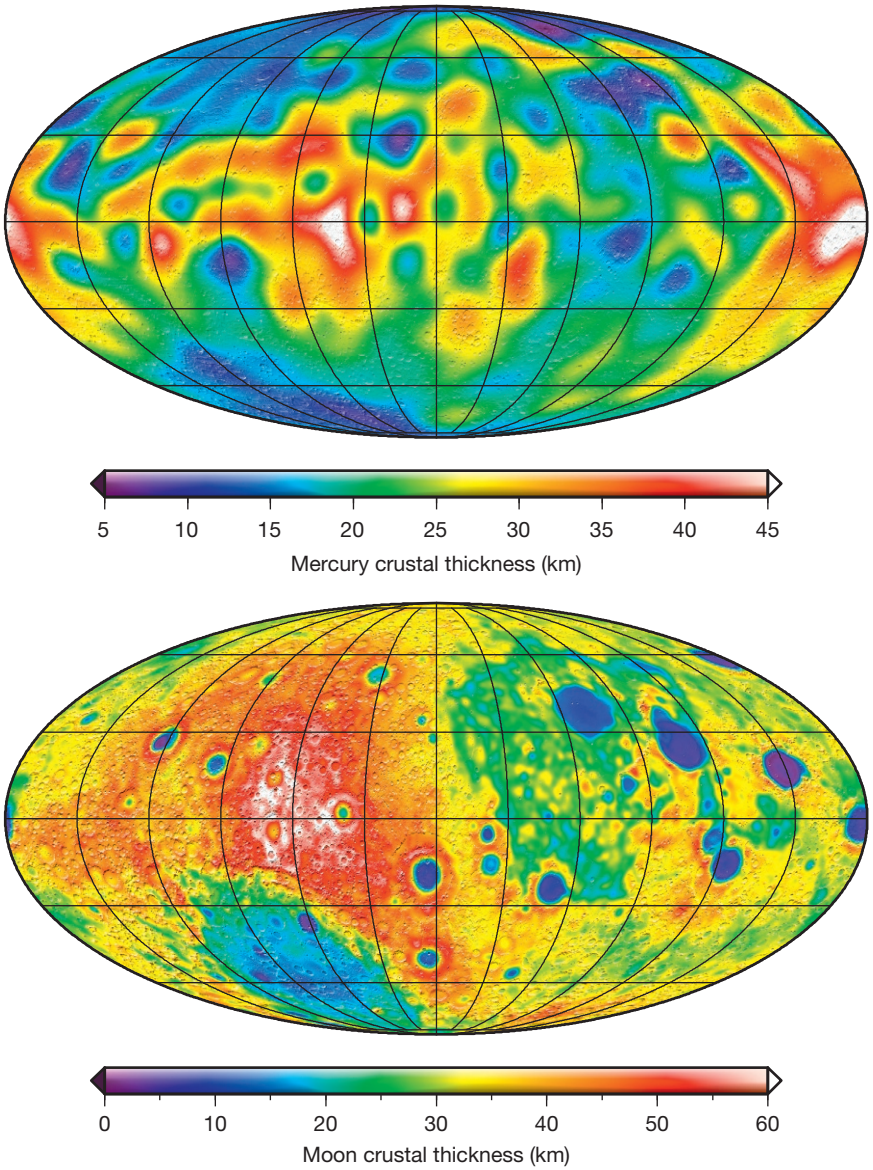

Figure 13 Crustal thickness models for Mercury and the Moon. Both images are in a Mollweide projection and are overlain by a gradient image derived from the surface topography. The central meridian is 180°E for Mercury and 90°W for the Moon.

compensated at these wavelengths, it is common to employ a model based on the condition of Airy isostasy for these regions. Assuming that the density of the crust is constant and using the condition of equal mass in crust–mantle columns, it is straightforward to show using eqn [35] that the transfer function between the potential and topographic coefficients is

$$Q_l = \frac{C_{lm}}{h_{lm}} = \frac{4\pi\rho_c R^2}{M(2l+1)}\left[1 - \left(\frac{R-T_c}{R}\right)^l\right] \qquad [39]$$

where ρ_c is the density of the crust and T_c is its mean thickness.

In practice, the GTR is determined by fitting the observations to a straight line within a region that is believed to be consistent with the employed model. By utilizing a plot of the predicted GTR versus T_c (obtained from eqns [37] to [39]), the crustal thickness can then be estimated for a given value of ρ_c. Nevertheless, as the GTR is influenced strongly by the longest wavelength components of the gravity and topography, several aspects need to be considered carefully when performing such an analysis.

It is first necessary to ensure that the entire signal of the geoid and topography are governed by the same compensation model. This can never be entirely satisfied, but certain anomalous long-wavelength features can sometimes be identified and removed. For instance, most planets and satellites possess significant rotational and/or tidal contributions to their degree-2 shape, and these signatures can be minimized by setting these coefficients to zero. For Mars, in addition to the degree-2 rotational signature, the longest wavelength components have been affected by the load and flexural response associated with the Tharsis province (see Phillips et al., 2001; Wieczorek and Zuber, 2004; Zuber and Smith, 1997).

Furthermore, as the degree-1 potential terms are zero when the gravitational field is referenced to the body's center of mass, any degree-1 topography that exists may need to be treated separately. Finally, as the GTR is determined largely by the longest wavelength components of the geoid and topography, it is necessary that the region of interest be sufficiently large when regressing the geoid and topography data.

10.05.6.2 Spectral Domain

Two major shortcomings associated with modeling the GTR are that only a single wavelength-independent parameter is used and the observed value could be biased by long-wavelength features that are unrelated to the assumed compensation model (such as lateral density anomalies in the mantle). An alternative modeling approach that largely bypasses these concerns is to model the relationship between the gravity and topography for a certain region in the spectral domain. As wavelength-dependent admittance and correlation functions are obtained, it is in principle possible to invert for several model parameters. The major shortcoming of this approach is that low spectral resolutions of planetary datasets can be particularly limiting when performing localized spectral analyses, as described in the following section. In this section, the basic concepts involved with global spectral analyses are described.

Let us presume that the potential and topography coefficients are related via an equation of the form

$$C_{lm} = Q_{lm} h_{lm} + I_{lm} \qquad [40]$$

where Q_{lm} is a linear nonisotropic transfer function and I_{lm} is that portion of the potential not described by the model. For simplicity, it will be assumed that I_{lm} is zero (though this assumption will be relaxed later) and that the topography is noise-free. Even though the aforementioned relationship is inherently nonisotropic, it is often useful to work with the power and cross power spectra of the gravitational field and topography (S_{hh}, S_{gg}, and S_{hg}), which only depend upon spherical harmonic degree l. The goal is to fit these three functions to those obtained from an appropriate model. In order to remove the model dependence of certain nuisance parameters, it is convenient to work with ratios of these three cross power spectra. Although several such ratios involving powers of these are possible, only two will be independent, and it is traditional to use the admittance and correlation spectra as defined previously by eqns [28] and [46]. If a model describing a planet's gravity and topography is to be considered successful, then it must satisfy both of these functions. If one or both of these functions cannot be fit for a given degree, then this is a clear indication that either the model assumptions are inappropriate for the region being investigated or the input datasets are not sufficiently accurate.

If one treats the lithosphere of a planet as a thin elastic spherical shell overlying a fluid interior (see Kraus, 1967), then a simple relationship exists in the spectral domain between the load on the lithosphere and its deflection (see Banerdt, 1986; Beuthe, 2008; Turcotte et al., 1981; Willemann and Turcotte, 1981). If loading at only a single interface is considered (either at or below the surface), then the transfer function in eqn [40] is isotropic (i.e., independent of m). For this situation, expressions for the admittance and correlation functions can be written schematically as

$$Z(l) = f(\rho_c, \rho_m, v, E, T_e, T_c, z, g, R) \qquad [41]$$

$$\gamma(l) = 1 \quad \text{or} \quad -1 \qquad [42]$$

where f denotes a functional dependence on the enclosed parameters. In particular, the admittance function depends explicitly on the crustal and mantle density, Poisson's ratio v, Young's modulus E, the elastic thickness T_e, the crustal thickness, the depth of the load z, the magnitude of the gravitational acceleration g, and the radius of the planet. For an isotropic transfer function Q_l, it is trivial to show that the degree correlation function (in the absence of noise) is equal to either $+1$ or -1, according to the sign of Q_l. This model has been amended by McGovern et al. (2002), Belleguic et al. (2005), and Grott and Wieczorek (2012) to include in-phase loads applied to and below the surface when the two are related linearly by a degree-independent constant. Such models would include an additional parameter $\mathcal{L}$, which is a function of the relative magnitudes of the surface and subsurface loads. Geologic situations where surface and subsurface loads might be perfectly correlated include isolated volcanoes and impact basins.

An alternative loading model that includes loads applied to and below the surface was developed by Forsyth (1985) in the Cartesian domain (see also Banks et al., 2001). In contrast to models that take the applied loads to be perfectly in phase, it was assumed that the phase differences of the applied surface and subsurface loads were random. Such an assumption might be expected to be reasonable for continental cratons where several geologic processes have operated over extended periods of time (such as erosion, sedimentation, and magmatism). In contrast to eqn [42], this model possesses a wavelength-dependent correlation function.

A general model that allows for an arbitrary phase relationship between the surface and subsurface loads has been developed by the author in spherical coordinates and can be schematically described by the following equations:

$$Z(l) = f(\rho_c, \rho_m, v, E, T_e, T_c, z, \mathcal{L}, \alpha_l, g, R) \qquad [43]$$

$$\gamma(l) = f'(\rho_c, \rho_m, v, E, T_e, T_c, z, \mathcal{L}, \alpha_l, g, R) \qquad [44]$$

where both f and f' represent generic functional dependencies. The phase relationship of the two loads is described by an additional parameter α that can possess values between 1 and -1 for correlated and anticorrelated loads, respectively. The expectation of α is given by the expression

$$\alpha_l = \frac{\sum_{m=-l}^{l} \langle \cos \Delta_{lm} \rangle}{(2l+1)} \qquad [45]$$

where Δ_{lm} denotes the phase difference between the two loads and $\langle \cdots \rangle$ is the expectation operator. For random phases, α is zero, and the model degenerates to that of Forsyth (1985). When the loads are perfectly in or out of phase by 0° or 180°, $\alpha = \pm 1$ and the model is analogous to that of McGovern et al. (2002) and Belleguic et al. (2005). A similar model was developed contemporaneously by Kirby and Swain (2009) in Cartesian geometry using a somewhat different approach and then later by Audet (2013) in spherical harmonics.

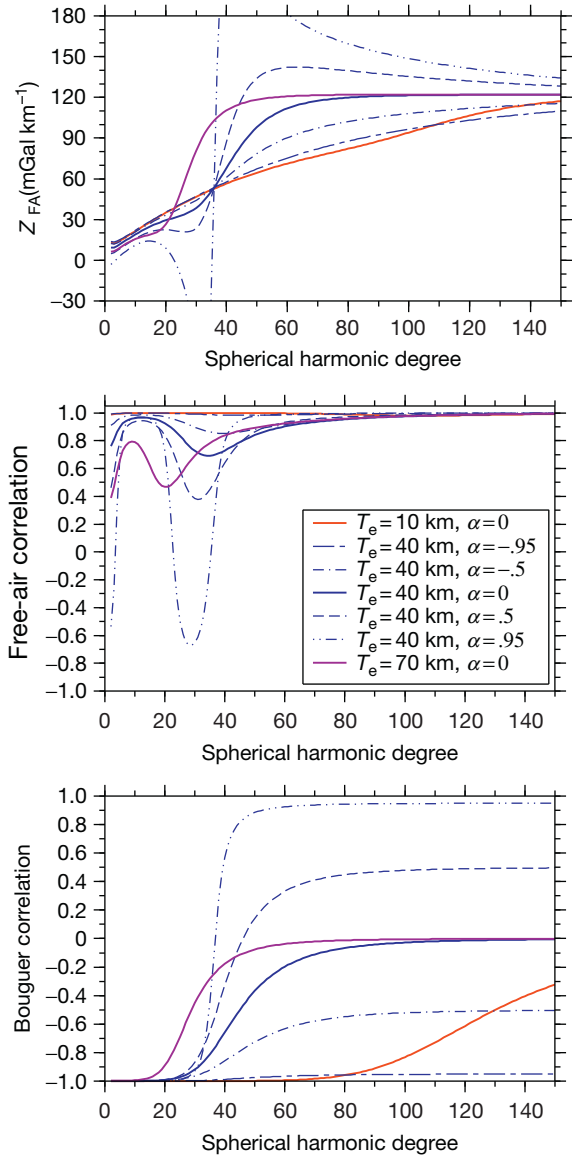

Figure 14 (Top) Free-air admittance, (middle) free-air correlation, and (bottom) Bouguer correlation, for a flexure model with equal magnitudes of applied surface and subsurface loads. Model parameters correspond to the planet Mars, with $T_c = z = 50$ km, $\rho_c = 2900$ kg m^{-3}, $\rho_m = 3500$ kg m^{-3}, and $E = 10^{11}$ Pa. The solid lines correspond to the case where the applied surface and subsurface loads have random phases (i.e., $\alpha = 0$), and the dashed lines correspond to the case where these loads are partially correlated.

Examples of the predicted free-air admittance and correlation functions are shown in Figure 14 for several values of the elastic thickness and phase parameter α. These models were generated using parameters typical for the planet Mars, and the magnitudes of the applied surface and subsurface loads were chosen to be equal. As is seen, these curves are strong functions of both the elastic thickness and α, and by considering both the admittance and correlation, it may be possible to separate the effects of the two. The free-air correlation function possesses low values over a restrictive range of wavelengths that is diagnostic of the elastic thickness. Furthermore, the free-air correlation function is seen to approach unity at high degrees ($l \gtrsim 100$). In practice, if a decline of the free-air correlation is observed with increasing degree, this is usually a good indicator of a loss of fidelity with the employed gravitational model. The predicted Bouguer correlation function is also shown for the same model parameters, and this shows a behavior similar to that predicted by the model of Forsyth (1985). It is noted that the Bouguer correlation asymptotically approaches the value of α with increasing degree. Whereas the Bouguer correlation is useful for interpretive purposes, its use is not advocated here because the Bouguer gravitational anomaly depends critically upon the value chosen for the crustal density, and this is in general not known a priori.

The preceding discussion assumed explicitly that the unmodeled gravitational signal I_{lm} in eqn [40] was identically zero. As mentioned in **Section 10.05.2.2**, if I_{lm} and the topography are uncorrelated, the expectation of the admittance will not be affected by the presence of such a signal. However, the expectation of the gravitational power spectrum will be biased upward by an additive constant S_{II}, and this will tend to bias the correlation function downward. In particular, the observed correlation function in the presence of noise is equal to

$$\gamma^{obs}(l) = \frac{\gamma(l)}{\sqrt{1 + S_{II}(l)/S_{gg}(l)}} \qquad [46]$$

where γ is the noise-free value.

Fortunately, any theoretical loading model can be easily modified to incorporate an unmodeled signal I_{lm} that is uncorrelated with the topography. It would be a simple matter to include S_{II} as an inversion parameter in a generic loading model such as eqn [44], though it is noted that this has not yet been attempted in the literature. While I_{lm} is commonly assumed to be gravitational measurement noise, this need not be the case. As described by McKenzie (2003), massive erosion or sedimentation of a lithosphere possessing surface and subsurface loads could give rise to a final state where the surface is perfectly flat but where gravitational anomalies are present. If this final state were taken as the initial condition of a *subsequent* loading event, then the initial gravitational signature (which is unrelated to the second loading model) would be expected to be uncorrelated with the subsequently generated topography.

Finally, it is important to reemphasize that if a given model of lithospheric loading is an accurate description of reality, it must fit both the admittance and coherence functions. If this cannot be done, then either the model or data must be inaccurate. Unfortunately, the vast majority of published investigations that use Forsyth-like loading models employ only the admittance or coherence function. The values of inverted parameters from such studies, while perhaps correct, need confirmation by analysis of the other function. Notable exceptions include the papers by Forsyth and coworkers (Bechtel et al., 1990, 1987; Ebinger et al., 1989; Forsyth, 1985; Pérez-Gussinyé et al., 2004; Phillips, 1994; Zuber et al., 1989). Similarly, many published investigations that employ a loading model with only surface or subsurface loads also ignore the correlation function, even though such models explicitly require this to be ± 1 when I_{lm} is zero.

10.05.7 Localized Spectral Analysis

The spherical harmonic functions represent a global basis, and the power spectrum as defined by eqn [9] is necessarily representative of the global properties of the function. In geophysics, however, it is reasonable to suspect that the spectral properties of the gravity and topography will vary as a function of position. For example, the elastic thickness may differ among geologic provinces as a result of their unique histories. Alternatively, it might arise that the data are known only locally and that one would like to estimate the power spectrum based exclusively upon these data. In this section, two methods are discussed that address these issues: One uses orthogonal windowing functions to form a multitaper spectral estimate, and the other uses spherical wavelets.

10.05.7.1 Multitaper Spectral Analysis

One way of obtaining localized estimates of a function's power spectrum is to first multiply the data by a localizing window (commonly referred to as a data taper) and then expand this windowed function in spherical harmonics (for a detailed discussion in the Cartesian domain, see Percival and Walden, 1993). However, as a result of the windowing procedure, the resultant power spectrum will differ from the true value. For the case where the input field is stationary and the spherical harmonic coefficients are governed by a zero-mean stochastic process, it can be shown that the expectation of the windowed power spectrum is related to the global spectrum by the following relation (Wieczorek and Simons, 2005, 2007):

$$\langle S_{\Phi\Gamma}(l)\rangle = \sum_{j=0}^{L} S_{hh}(j) \sum_{i=|l-j|}^{l+j} S_{fg}(i)\left(C^{l0}_{i0j0}\right)^2 \qquad [47]$$

Here, h represents an arbitrary window bandlimited to degree L, Φ, and Γ are the windowed fields hf and hg, respectively, and the last symbol in parentheses is a Clebsch–Gordan coefficient (these are related to the Wigner $3-j$ symbols and are proportional to the integral of three Legendre functions; see Varshalovich et al., 1988). The expectation of the windowed power spectrum $S_{\Phi\Gamma}$ is seen to be related to the global spectrum by a smoothing operation reminiscent of a convolution.

For a localized spectral analysis, the question arises naturally as to what form the localizing window should take. In order to spatially localize the data, it is clear that the amplitude of the window (or its power) should be near zero outside the region of interest. Furthermore, as a result of the convolution-like relationship between the global and windowed spectra, the bandwidth L of the window should be as small as possible in order to limit this spectral smoothing. Slepian and coworkers (see Slepian, 1983) posed and solved this problem in Cartesian geometry by finding those windows whose power was concentrated optimally in a specified region. Using this same criterion, Wieczorek and Simons (2005) and Simons et al. (2006) solved for those bandlimited windows on the sphere that are concentrated optimally within a spherical cap. The case of arbitrary regions was treated by Simons et al. (2006), and the case where data are absent at the poles (the polar gap problem) was treated by Simons and Dahlen (2006).

This optimization problem reduces to a simple eigenvalue equation whose solution yields a family of $(L+1)^2$ orthogonal data tapers; the quality of the concentration is given by the corresponding eigenvalue, λ, which is the fractional power of the function within the region of interest. As an example, for a concentration region specified by a spherical cap with an angular radius of 30°, as shown in **Figure 15**, 34 windows exist with a bandwidth $L=29$ that concentrate more than 99% of their power within the region of interest.

Though it is common to use a single localization window when performing a localized spectral analysis, the use of multiple tapers, as pioneered by Thomson (1982) in the Cartesian domain, can be highly advantageous. The multitaper estimate is defined as the weighted sum of spectra obtained from using K well-localized orthogonal tapers:

$$S^{(mt)}_{\Phi\Phi}(l) = \sum_{k=1}^{K} a_k S^{(k)}_{\Phi\Phi}(l) \qquad [48]$$

The values of the weights are usually assigned to be either $1/K$ or proportional to $1/\lambda_k$, but these can be chosen to also minimize the variance of the estimate (Wieczorek and Simons, 2007). The benefits of using a multitaper estimate are several fold. First, the cumulative energy of orthogonal tapers will be nearly constant across the region of interest, whereas the energy of any single window will nonuniformly cover the concentration region. Because of this, a multitaper average will be more representative of the data than that of a single taper. Second, while it is generally not possible to obtain the expectation of the localized spectrum since there is usually only a single field available for analysis, the spectral estimates obtained from orthogonal tapers are nearly uncorrelated, and their average can be considered as an approximation of the expectation. Finally, by using multiple tapers, it is possible to make an estimate of the uncertainty associated with a given spectral estimate; this is expected to decrease as approximately $1/\sqrt{K}$ (Wieczorek and Simons, 2005, 2007).

In performing a localized spectral analysis, there are several factors that need to be considered. First, it is noted that if the fields f and g of eqn [47] are known to a maximum spherical harmonic degree of L_{fg}, then only the first $L_{fg}-L$ windowed spectral estimates are reliable. Second, those localized spectral estimates with degrees less than L are heavily biased and possess relatively large uncertainties, making these of little use for geophysical analysis. Third, while a multitaper spectral analysis is generally preferable to using a single taper, the aforementioned two concerns present serious limitations when working with the relatively low-resolution gravity fields of Mercury, Venus, and Mars. Depending on the size of the concentration region, it may be infeasible to use the larger bandwidths that are required for obtaining several well-concentrated tapers.

Finally, when comparing model results to observations, it is emphasized that the two must be windowed in the same manner (e.g., Pérez-Gussinyé et al., 2004). If the analysis is performed by generating forward models of the gravity field using the known topography, then it is necessary to localize these functions in the same manner as the data. Alternatively, if no explicit expression exists for Q_{lm} (as in the model of Forsyth (1985) and that presented in **Section 10.05.6.2**, both of which are statistical in nature), then it is necessary to window the

predicted (cross) power spectra using eqn [47] before calculating the theoretical admittance and correlation functions.

10.05.7.2 Wavelet Analysis

An alternative approach of performing a localized spectral analysis is to use spherical wavelets. A wavelet analysis differs from a multitaper analysis in that (1) the function is multiplied by a wavelet of a given size and integrated over all space, as opposed to being multiplied and then expanded in spherical harmonics, and (2) the wavelet scalogram (the analog of the power spectrum) is a function of the wavelet scale (i.e., size) and not spherical harmonic degree. Whereas the multitaper spectral analysis approach is best when the function is known to be locally stationary within the analysis region, wavelet analyses are better suited to truly nonstationary processes.

The wavelet transform for real functions is defined as the inner product of a function f with a wavelet ψ of scale s centered at position $\hat{\mathbf{r}}$ and with angular orientation γ about this axis:

$$\tilde{f}(s, \hat{\mathbf{r}}, \gamma) = \int_\Omega f(\theta', \phi') \psi_{s,\hat{\mathbf{r}},\gamma}(\theta', \phi') \mathrm{d}\Omega' \qquad [49]$$

The wavelet transform can be defined either to be continuous in scale s or to be composed of discreet scales. By expressing both f and ψ in spherical harmonics,

$$\tilde{f}(s, \hat{\mathbf{r}}, \gamma) = 4\pi \sum_{l=0}^{L} \sum_{m=-l}^{l} f_{lm} \psi_{lm}(s, \hat{\mathbf{r}}, \gamma) \qquad [50]$$

where L is the smaller of the spherical harmonic bandwidth of f and ψ (the product is zero beyond the bandwidth of either function). If the wavelets are zonal functions, the wavelet transform is

$$\tilde{f}(s, \hat{\mathbf{r}}) = 4\pi \sum_{l=0}^{L} \sum_{m=-l}^{l} f_{lm} \Psi_l(s) \sqrt{\frac{1}{2l+1}} Y_{lm}(\theta, \phi) \qquad [51]$$

where Ψ_l are the spherical harmonic coefficients of the zonal wavelet centered at the north pole. For zonal wavelets, the wavelet transform is equivalent to the spatial convolution of f and ψ. The wavelet transform can be calculated rapidly everywhere using fast Fourier transform techniques and Wigner rotation matrices (Wandelt and Gòrski, 2001).

The wavelet cross scalogram of two real functions f and g is defined as

$$P_{fg}(s, \hat{\mathbf{r}}, \gamma) = \tilde{f}(s, \hat{\mathbf{r}}, \gamma) \tilde{g}(s, \hat{\mathbf{r}}, \gamma) \qquad [52]$$

If it is assumed that the two functions f and g are stochastic stationary processes, it can be shown that the expectation of this expression is related to the power spectrum of the wavelet and the cross power spectrum of f and g by

$$\langle P_{fg}(s)\rangle = (4\pi)^2 \sum_{l=0}^{L} \frac{S_{fg}(l) S_{\Psi_s\Psi_s}(l)}{2l+1} \quad [53]$$

where $S_{\Psi_s\Psi_s}$ is the power spectrum of the wavelet of scale s. This fundamental relation is analogous to eqn [47] as used in localized spectral analyses and quantifies how the power spectrum of the data is modified by the window spectrum when forming the wavelet cross scalogram.

In general, wavelets should have a zero mean, they should be localized in space in order to study nonstationary processes, and they should be localized in the spectral domain in order to best extract the frequency content of the signal (cf. eqn [53]). A multitude of wavelet families have been constructed, including those that are zonal (Chambodut et al., 2005; Fengler et al., 2007; Freeden and Windheuser, 1997; Guilloux et al., 2009; Holschneider et al., 2003; Holschneider and Iglewska-Nowak, 2007; Li, 1999; Michel and Wolf, 2008; Panet et al., 2011; Schmidt et al., 2007; Wiaux et al., 2007) and directional (Audet, 2011, 2013; McEwen et al., 2007). Once the family of wavelets has been constructed for each scale s, it is straightforward to construct the wavelet transform. Nevertheless, the best manner to construct a family of wavelets on the sphere is not trivial. The biggest problems consist of how to discretize the wavelets as a function of scale, how to most optimally represent the data by the smallest number of wavelet coefficients as possible, and how to minimize correlations between the wavelet coefficients (e.g., Freeden and Windheuser, 1997; Narcowich and Ward, 1996). A perhaps more daunting problem is deciphering the spherical wavelet literature itself: many of these papers are highly mathematical, the notation is highly variable among authors, and the papers span a wide range of disciplines and journals.

10.05.8 Summary of Major Results

10.05.8.1 Earth

The gravity and topography of Earth have been used extensively to decipher the rheological properties of the crust and upper mantle. The literature is voluminous, and the reader is referred to several reviews in volume 8 of this series, Watts (2001), and the references in the papers cited in the succeeding text. Here, only a few subjects will be touched upon that bear relevance to investigations of Venus, Mars, Mercury, and the Moon. These include modeling of the elastic thickness of the oceanic and continental lithosphere, inelastic flexural modeling, and the modeling of dynamic topography and geoid signatures associated with mantle convection.

Flexural modeling of the oceanic lithosphere is relatively simple in that loading is primarily a result of the construction of isolated shield volcanoes. Elastic thickness estimates have been obtained by modeling the topographic and gravity signatures of these features, and it is widely accepted that the elastic thickness is dependent primarily upon the age of the plate at the time of loading, with T_e being less than about 45 km (for a review, see Watts, 2001). In particular, a plot of the elastic thickness versus age of the lithosphere at the time of loading resembles the time dependence of the depth to an isotherm (~300–600 °C) predicted from a plate cooling model (see Watts and Zhong, 2000). This suggests that the flexural signature has been 'frozen' into the lithosphere as it cooled and that subsequent long-term viscoelastic relaxation has been relatively unimportant. Nevertheless, a description of the initial short-term subsidence of the lithosphere (i.e., the first few 10 s of ka) requires the use of a viscoelastic model, and given the relatively restricted age range of oceanic lithosphere (<200 Ma), it is difficult to discern if viscoelastic relaxation would be important at longer timescales. It is important to note that most flexural modeling of features on the other terrestrial planets has been for loads that were emplaced on the lithosphere over a billion years ago.

Investigations of the continental elastic thickness have been more contentious. Part of the difficulty arises because the importance of subsurface loading, and the phase relationship of the surface and subsurface loads, is not known a priori (see **Section 10.05.6.2**). A loading model was developed by Forsyth (1985) that took into account both surface loading and subsurface loading under the assumption that the two were uncorrelated, and application of this method has yielded elastic thicknesses in the broad range from about 5 to 150 km (Bechtel et al., 1990, 1987; Ebinger et al., 1989; Forsyth, 1985; Kirby and Swain, 2009; Pérez-Gussinyé et al., 2004, 2009; Zuber et al., 1989). There is some controversy as to whether the values greater than ~25 km are reliable (compare McKenzie, 2003 with Watts and Burov, 2003), but this debate will not be settled definitively until investigators fit both the admittance and correlation functions simultaneously while taking into account partially correlated loads and unmodeled gravitational signals (see **Section 10.05.6.2**). Furthermore, some studies that have inverted for the elastic thickness using multitaper spectral analysis and wavelet techniques have done so using a methodology that is not entirely correct. In particular, as both windowing and wavelet approaches return a modified form of the power spectrum (cf. eqns [47] and [53]), it is necessary to compare these modified spectra with suitably modified theoretical spectra, which is not always done. Regardless, these methods have convincingly shown that the elastic thickness of some continental regions is not always isostropic (e.g., Kirby and Swain, 2006; Simons et al., 2003, 2000), which is an assumption common to most studies.

The majority of investigations that model lithospheric flexure assume that the lithosphere is perfectly elastic, but elastic stresses are often predicted to be in excess of the strength of geologic materials. A simple modification to the elastic flexure equation that takes this into account is to replace the elastic bending moment–curvature relationship with one that is based upon an elastic–perfectly plastic (EP) model of the lithosphere's yield strength (e.g., Burov and Diament, 1995; Mueller and Phillips, 1995). In particular, the strength of the upper crust is limited by brittle failure, and stresses in the lower crust and mantle are limited by their ductile strength for a specified strain rate. Predicted flexural profiles are time-invariant and can sometimes differ significantly from those of the perfectly elastic model. As the ductile strength is temperature-dependent, these results are sensitive to the assumed lithospheric temperature gradient.

A more realistic model of lithospheric deformation uses a time-dependent elastoviscoplastic (EVP) formulation (e.g., Albert and Phillips, 2000; Albert et al., 2000; Brown and

Phillips, 2000). The main advantage of these models is that the strain rates are calculated explicitly, as opposed to assumed as in the EP models. Though the best-fit EP and EVP flexural profiles can be quite similar, it is not clear a priori how one should estimate the characteristic strain rate that is required for the EP model without running a full EVP simulation (Albert et al., 2000). The EVP models show that significant decoupling of stresses may occur between the crust and mantle if the lower crust is sufficiently weak (e.g., Brown and Phillips, 2000). When this occurs, the effective elastic thickness decreases; the exact value is highly dependent upon the crustal thickness, load magnitude, and assumed rheology of the crust and mantle. In contrast, when the lower crust is strong, the maximum achievable effective elastic thicknesses are consistent with the depth of an ~700 °C isotherm obtained from a lithospheric cooling model. Flexural modeling of a volcano growing on a cooling lithosphere shows that the effective elastic thickness is 'frozen' into the lithosphere shortly after volcanic construction is complete (Albert and Phillips, 2000).

Finally, in addition to near-surface crustal thickness and density variations, significant gravity and topography signatures can be generated by dynamic processes in the mantle, such as beneath hot spots and subduction zones. Though there are few, if any, convincing examples of plate subduction on the other terrestrial planets, hot spots similar to Earth are believed to exist on both Venus and Mars. Dynamic modeling of plumes shows that the major variable controlling the surface gravity and topography signatures is the depth dependence of the mantle viscosity. In the absence of a shallow low-viscosity asthenosphere, convective stresses generated at depth are coupled efficiently to the surface, generating large signals and large corresponding effective depths of compensation. However, the inclusion of a shallow low-viscosity zone can reduce these signatures significantly, giving rise to shallower apparent depths of compensation (e.g., Ceuleneer et al., 1988; Robinson and Parsons, 1988). Joint inversions utilizing mantle density anomalies from seismic tomography and estimates for the dynamic topography signal imply the existence of a low-viscosity zone somewhere in the upper mantle and a gradual increase in viscosity with depth by an order of magnitude in the lower mantle (e.g., Panasyuk and Hager, 2000).

10.05.8.2 Venus

Our knowledge of Venus has dramatically improved since the acquisition of gravity, topography, and SAR imagery by the Magellan mission between 1990 and 1994. The size and bulk density of Venus were known beforehand to be similar to that of Earth, but this planet was found to differ dramatically in that it lacks any clear sign of plate tectonics. A major unanswered question is how this planet loses its internal heat and whether or not this process is episodic or uniform in time. Geophysical analyses have been used to constrain the crustal and elastic thickness, and the latter has been used to place constraints on the temperature gradient within the lithosphere. Reviews concerning the geophysics of this planet can be found in Phillips et al. (1997), Grimm and Hess (1997), Schubert et al. (1997), and Nimmo and McKenzie (1998).

The crustal plateaus of Venus have generally low-amplitude gravitational and topographic signatures within their interiors and low GTRs. With the exception of Ishtar Terra, these regions are potential candidates for being isostatically compensated. Assuming that the surface topography is compensated at a single interface, Grimm (1994) obtained best-fit apparent depths of compensation between 20 and 50 km for Alpha, Tellus, Ovda, and Thetis Regiones. These values are plausibly interpreted as representing the depth of the crust–mantle interface. Analyses of GTRs by Kucinskas and Turcotte (1994), Moore and Schubert (1997), and James et al. (2013) obtained zero-elevation crustal thicknesses between about 40 and 80 km for Alpha, Ovda, Tellus, and Thetis Regiones. If any portion of the geoid and topography were to result from Pratt or thermal compensation, the obtained crustal thicknesses would represent an upper bound. A spectral admittance study by Phillips et al. (1997) obtained a slightly thinner crustal thickness of 38 ± 9 km for the region of Atla Regio (see also Phillips, 1994).

In contrast to the majority of the highland plateaus, large apparent depths of compensation and GTRs have been found for the volcanic rises (Kucinskas and Turcotte, 1994; Moore and Schubert, 1995, 1997; Smrekar, 1994) and Ishtar Terra (Grimm and Phillips, 1991; Hansen and Phillips, 1995; Moore and Schubert, 1997). These values are not consistent with compensation occurring solely by crustal thickening, but require some form of dynamic support from the mantle via stresses induced by ascending mantle plumes (e.g., Vezolainen et al., 2004) or substantial thinning of a thick (~300–600 km) thermal lithosphere (Kucinskas and Turcotte, 1994; Moore and Schubert, 1995, 1997; Orth and Solomatov, 2011). If a low-viscosity asthenosphere were present at shallow mantle depths, as is the case of Earth, the predicted GTRs and apparent depths of compensation resulting from dynamic support would be considerably smaller than measured as a result of the decoupling of stress between the lithosphere and mantle (e.g., Kiefer and Hager, 1991; Kiefer et al., 1986). This seems to imply that in contrast to Earth, Venus lacks a low-viscosity zone (Huang et al., 2013; Pauer et al., 2006), which is most likely a result of a volatile-poor mantle. Modeling by Pauer et al. (2006) suggests that the viscosity of the Venusian mantle could increase by a factor of about 10–80 from the upper to lower mantle, similar to that of Earth. A strong coupling of stress between the lithosphere and convecting mantle is the likely cause of the high spectral correlation between gravity and topography for the lowest spherical harmonic degrees of Venus (contrast **Figures 2** and **4**).

An additional constraint concerning the thickness of the Venusian crust is related to its compositional buoyancy. If the crust were basaltic in composition, this material would undergo a phase transition at high pressure to the more dense mineral assemblage of eclogite (e.g., Grimm and Hess, 1997). This material could potentially delaminate from the base of the crust as a result of its high density, and the depth of this phase transition might thus constrain the maximum achievable crustal thickness. For a MORB composition, the eclogite phase transition is predicted to occur at depths of ~70–120 km (see Ghent et al., 2004) for linear temperature gradients of 5 and 15 K km^{-1}, respectively.

The crustal thickness model presented in **Figure 12** has thicknesses near 70 km only in the highland plateaus of Ishtar Terra and Ovda and Thetis Regiones, suggesting that crustal delamination could have occurred in these regions. The

highland crust is almost exactly twice as thick as the lowland crust, which could potentially arise by the obduction of one plate over another. In contrast to Mercury, Mars, and the Moon, no large impact basins are found on this planet as a result of the relatively young age of its surface (~240 Ma; Le Feuvre and Wieczorek, 2011). This crustal thickness model assumed an average thickness of 35 km and did not consider density anomalies beneath the crust–mantle interface. An alternative model was developed by Orth and Solomatov (2012) who assumed that variations in lithospheric thickness were isostatically compensated and that the remaining signal was a result of isostatic variations in crustal thickness. James et al. (2013), in contrast, constructed a global crustal thickness model by assuming that the observed surface topography and gravitational potential were a result of isostatically compensated crust and dynamic relief arising from mantle density anomalies below an elastic lid.

Elastic thickness estimates have been obtained for a variety of features based exclusively on topographic profiles that are indicative of flexure. The benefit of using topography alone is that small features can be investigated that are not resolved in the current gravity model. Elastic thicknesses of 11–25 km have been obtained by modeling the Freyja Montes foredeep (Sandwell and Schubert, 1992; Solomon and Head, 1990) and ~10–60 km for potential flexural bulges outboard of coronae (Sandwell and Schubert, 1992). Additional features modeled by Johnson and Sandwell (1994) yield elastic thicknesses of 10–40 km, and potential subduction-related sites possess a range of 6–45 km (Schubert and Sandwell, 1995). Predicted stresses are largest where the plate curvature is greatest, and faulting is generally visible in the Magellan SAR imagery at these locations. Modeling by Barnett et al. (2002) yielded best-fit elastic thicknesses that are consistent with the aforementioned studies. Modeling the location of concentric faulting around Nyx Mons (a volcano in Bell Regio) implies a best-fit elastic thickness of ~50 km (Rogers and Zuber, 1998). It is important to note that the assumption of a perfectly elastic rheology may be grossly inappropriate for some features. For instance, the magnitude of the flexure-induced bulge south of Artemis Chasma implies that significant yielding has occurred within the lithosphere, and inelastic modeling by Brown and Grimm (1996) shows that a significant compressive in-plane force is required at this locale.

The elastic thickness has also been estimated for various regions of Venus through a combined analysis of gravity and topography data in the spectral domain. However, the majority of these investigations have fit only the admittance or coherence functions, but not both simultaneously (e.g., Anderson and Smrekar, 2006; Barnett et al., 2000, 2002; Hoogenboom et al., 2005, 2004; Lawrence and Phillips, 2003; McKenzie, 1994; McKenzie and Nimmo, 1997; Simons et al., 1994, 1997; Smrekar, 1994; Smrekar et al., 2003; Smrekar and Stofan, 1999). The robustness of the inverted parameter values, the fidelity of the gravity model, and the appropriateness of the loading model are all difficult to assess in these studies. One exception is that of Phillips (1994) who investigated the lithospheric properties of Atla Regio, which is believed to be an active hot spot based on its geomorphology and previously determined large apparent depths of compensation. Using the loading model of Forsyth (1985), which assumes uncorrelated surface and subsurface loads, it was shown that a single mode of compensation could not explain the entire wavelength range of the admittance and coherence functions. An inversion utilizing only the short wavelengths yielded a crustal thickness of 30 ± 13 km and an elastic thickness of 45 ± 3 km. Whereas surface loading by the volcanic constructs in this area dominates, about 10% of the load is required to be located at shallow depths within the crust. For the long-wavelength range, only the depth of the subsurface load was well constrained with a value near 150 km, and the elastic thickness was constrained only to be less than 140 km.

It is possible to place constraints on the crustal temperature gradient at the time of loading either by using the obtained elastic thicknesses or by forward modeling of inelastic flexure. The basic approach is to match the bending moment implied by the elastic model to that predicted by an inelastic rheology (McNutt, 1984). The obtained temperature gradient estimates lie in the rather broad range of 3–26 K km^{-1} (Brown and Grimm, 1996; Johnson and Sandwell, 1994; Phillips, 1994; Phillips et al., 1997; Sandwell and Schubert, 1992), but the majority of these lie on the low end, between ~4 and 10 K km^{-1}. This is considerably lower than the expected Earth-scaled temperature gradient of ~15 K km^{-1} (e.g., Phillips, 1994), especially when considering that some of these estimates were obtained where an underlying mantle plume might be expected. Though such calculations are critically dependent on the validity of the inelastic strength model, the assumed strain rate, and the depth dependence of temperature, these results seem to imply that the background heat flow of Venus is much less than would be expected by analogy to Earth. Such an interpretation is consistent with a model in which the Venusian lithosphere formed catastrophically ~500–1000 Mya and has since been cooling conductively (cf. Moresi and Solomatov, 1998; Parmetier and Hess, 1992; Turcotte, 1995). However, such a model is not required, or even preferred, by the cratering history of the Venusian plains (Hauck et al., 1998).

10.05.8.3 Mars

Following the acquisition of high-resolution gravity and topography data from the MGS and Mars Odyssey missions, a number of studies have been published bearing on the crustal and lithospheric structure of Mars. These investigations have placed constraints on the thickness of the Martian crust, the elastic thickness, and the crustal density and also imply the existence of dynamic support of topography and buried mass anomalies. Reviews concerning the gravity, topography, and crust of Mars can be found in Esposito et al. (1992), Banerdt et al. (1992), Zuber (2001), Wieczorek and Zuber (2004), Nimmo and Tanaka (2005), and Grott et al. (2013).

The average thickness of the Martian crust has been constrained by the analysis of GTRs over the ancient southern highlands. After removing the long-wavelength flexural and load signatures associated with the Tharsis province, a zero-elevation thickness of 57 ± 24 km was obtained under the assumption of Airy isostasy (Wieczorek and Zuber, 2004). This range of values is consistent with estimates based upon the viscous relaxation of topography (Nimmo and Stevenson, 2001; Zuber et al., 2000b) and geochemical mass-balance arguments, both of which require the crust to be less than ~100 km thick (see Wieczorek and Zuber, 2004). Crustal

thickness modeling further requires the mean thickness of the crust to be greater than about 25 km (Pauer and Breuer, 2008).

A global model of the crustal thickness of Mars has been constructed by Neumann et al. (2004) by assuming a mean thickness of 45 km (see **Figure 12**). If the assumption of a constant density crust is correct, the crust of the southern highlands is predicted to be thicker by about 30 km than the northern lowlands. However, if the northern lowland crust is denser than the southern highlands, as implied by the results of Belleguic et al. (2005), then the actual crustal thickness difference could be significantly less. The Tharsis province is seen to possess a relatively thick crust, indicative of prolonged volcanic construction, whereas the crust beneath the major impact basins is thinned and in some places nearly absent.

Localized spectral admittance and correlation spectra have been modeled in spherical coordinates for various regions using the techniques of Simons et al. (1997) and Wieczorek and Simons (2005). In the investigations of McGovern et al. (2002, 2004), Belleguic et al. (2005), Wieczorek (2008), Grott and Wieczorek (2012), and Beuthe et al. (2012), a thin elastic spherical shell loading model was employed that depended upon the shell's elastic thickness, the load density, the crustal density, and the ratio of the magnitudes of subsurface and surface loads, which were assumed to be in or out of phase by 0° or 180°. When the load density differs from that of the crust, the methodology of Belleguic et al. (2005) is more accurate, and their results are here emphasized.

Of all the parameters considered by Belleguic et al. (2005) when modeling the major Martian volcanoes, the load density is in general the best constrained. For the Tharsis Montes and Elysium rise, values of $\sim 3200 \pm 100\ \mathrm{kg\ m^{-3}}$ were obtained. After accounting for a few-percent porosity, this range is consistent with density estimates of the Martian meteorites, which are thought to be derived from these regions based on their young ages. Elastic thickness estimates are somewhat variable but were found to lie between about 50 and 100 km when only surface loads were considered. However, when both surface and subsurface loads were modeled, only upper and lower bounds could be specified for most regions. The crustal density was constrained only beneath the Elysium rise (which is located in the northern lowlands) and was found to be identical to the density of the superposed load. Combined modeling of GTRs and crustal thickness suggest a maximum density of about $3020\ \mathrm{kg\ m^{-3}}$ for the southern highlands, which is consistent with the value of $3000\ \mathrm{kg\ m^{-3}}$ suggested by Neumann et al. (2004) based on rock compositions at the Mars Pathfinder site. If the crustal density beneath the Elysium rise is representative of the northern lowlands, then this implies a hemispheric dichotomy in crustal composition. This result is consistent with geochemical maps obtained from the Mars Odyssey gamma-ray spectrometer that show the northern lowlands possess a higher iron concentration than the southern highlands (Taylor et al., 2006). The low elevations of the northern plains could thus be a partial result of Pratt compensation. Finally, the inclusion of less dense subsurface loads (either compositional or thermal in origin) improved the misfit between the modeled and observed admittance functions.

In the localized admittance study of Beuthe et al. (2012), two-stage loading models were employed to investigate how the elastic thickness and load density varied with time. This loading model could fit the data and models with single-stage top and bottom loading, calling into question the necessity of subsurface loading. Using similar localized admittance techniques, density and elastic thickness have been estimated at other regions on the planet. For the isolated low-relief volcano Tyrrhena Patera, Grott and Wieczorek (2012) obtained a density between 2960 and $3500\ \mathrm{kg\ m^{-3}}$, which is consistent with the Tharsis and Elysium volcanoes, and an elastic thickness that is less than 28 km. Zuber et al. (2007) and Wieczorek (2008) investigated the ice-rich south polar layered deposits and found densities close to $1250\ \mathrm{kg\ m^{-3}}$.

Elastic thickness estimates for other locales have been determined using a variety of techniques, but these generally contain a larger number of assumptions. Modeling of the geologically inferred flexural moat of the northern polar cap suggests an elastic thickness between 60 and 120 km (Johnson et al., 2000). Faults surrounding the Isidis impact basin imply elastic thicknesses between 100 and 180 km at the time of loading (Ritzer and Hauck, 2009). If the topography of the dichotomy boundary is flexural in origin, with loading in the northern plains, then elastic thicknesses of ~31–36 km are implied (Watters, 2003). Cartesian admittances were analyzed in several other studies (Hoogenboom and Smrekar, 2006; McKenzie et al., 2002; Milbury et al., 2009; Nimmo, 2002), but the validity of the loading model was not quantified by calculating theoretical correlation functions. A summary of how elastic thickness constrains Martian heat flow can be found in Grott et al. (2013).

One distinctive feature of Mars is the large geoid and topography signals associated with the Tharsis province (e.g., Phillips et al., 2001). Two possible end-member explanations for this observation are either that it is a result of voluminous extrusive lavas that are partially supported by the lithosphere or that it is a result of dynamic topography associated with an underlying plume. Viscoelastic modeling of the geoid and topography response to internal buoyant loads implies that a plume is incapable of producing the totality of the observed signals (Roberts and Zhong, 2004; Zhong, 2002). By modeling the contributions of both surface and plume signals with a method that approximates a viscoelastic response, the degree-2 and degree-3 GTRs imply that a plume can account for only ~15% and 25% of the geoid and topography signals, respectively. Using a modified approach that includes all spherical harmonic degrees, Lowry and Zhong (2003) inverted for the relative contributions of surface and internal loads and found that a plume could account only for a maximum of ~25% and 50% of the observed geoid and topography, respectively.

Finally, it is noted that buried mass anomalies can be investigated by examination of the residual gravity field after subtraction of an appropriate reference model. By modeling the gravity field of the Syrtis Major region by surface loading of an elastic shell, an unmodeled localized density anomaly was found beneath this volcanic province. The amplitude of this unmodeled anomaly is consistent with the presence of dense cumulates of an extinct magma chamber (Kiefer, 2004). Using a similar technique, buried mass anomalies have also been inferred along the portions of the dichotomy boundary (Kiefer, 2005).

10.05.8.4 Mercury

Our understanding of Mercury is currently being revolutionized by the analysis of data from the MESSENGER spacecraft.

At the time of this writing, the initial analyses have just been published, and more result will soon follow.

Mercury is somewhat similar to the Moon in that its surface records billions of years of impact cratering. One striking aspect concerning the topographic expression of the largest impact basins is that they are not as topographically distinct as those found on the Moon and Mars. Many of these basins have shallower than expected depths (Mohit et al., 2009), and others have been deformed topographically. One clear example of basin deformation that postdates the impact event is the topographic bulge in the northern portion of the Caloris basin that is higher than most of its topographic rim (Zuber et al., 2012). Together, these observations suggest some form of modification by either mantle convection or crustal viscous relaxation (Mohit et al., 2009).

The Caloris impact basin is clearly associated with a positive gravitational anomaly, similar to the mascon basins on the Moon. Few other basins have corresponding gravitational anomalies, but this could be an artifact of the low resolution of the current gravity model. Crustal thickness modeling shows that the Caloris, Budh, and Sobkou basins are associated with a thinned crust (Smith et al., 2012). However, little is known about the average thickness of the crust, which is important for understanding the bulk silicate composition of the planet. Estimates of the depths of faulting constrain the depth of the brittle–ductile transition, and when combined with an estimate of the melting temperature of the base of the crust, an average crustal thickness less than 140 km is required (Nimmo and Watters, 2004).

The lithospheric thickness of Mercury appears to have varied over time. Many regions of ancient high-standing topography do not possess any significant gravitational anomaly, indicating that they were likely in a state of isostatic compensation when they formed. In contrast, a positive gravitational anomaly is associated with a domical rise in the northern lowlands, and modeling of this feature implies that the lithosphere had an elastic thickness of 70–90 km at the time of its formation (Smith et al., 2012). As a result of Mercury's eccentric orbit and 3/2 spin–orbit resonance, the average temperature of the surface has strong variations in both latitude and longitude, with two hot 'poles' being located at 0° and 180° on the equator. These temperature variations are predicted to give rise to long-wavelength variations in the thickness of the lithosphere, with variations in the mechanical thickness approaching 80 km between ±90°N and the equatorial hot poles (Williams et al., 2011).

10.05.8.5 The Moon

Analyses of the gravitational field of the Moon have been hindered historically by the lack of direct tracking data over the lunar farside hemisphere. This problem was rectified only recently by the collection of four-way tracking data from the Kaguya (2007) mission and intersatellite range-rate measurements from the Gravity Recovery and Interior Laboratory (2011) mission. Together with altimetric data and stereo imagery collected by the LRO and Kaguya missions, it can be said that the gravity and topography of the Moon are known better in a global sense than any other terrestrial object. These data have permitted a wide range of investigations, including the mapping of crustal thickness variations, studies of giant impact basins, and the mapping of subsurface density anomalies. A comprehensive review of results predating the GRAIL, LRO, and Kaguya missions can be found in Wieczorek et al. (2006).

The observed gravity signal at short wavelengths, where lithospheric flexure is unimportant, should be almost entirely a result of relief along the surface (cf. **Figure 14**). Wieczorek et al. (2013) used this observation to estimate the bulk density of the lunar highland crust. The obtained value of 2550 kg m^{-3} was substantially lower than the expected grain density of about 2900 kg m^{-3}, and this implies the existence of about 12% porosity in the upper crust. Although the depth dependence of porosity is not well constrained, it must extend at least several kilometers below the surface and perhaps into the upper mantle. These high porosities are almost certainly a result of fractures generated by billions of years of impact cratering and are consistent with impact-induced porosities associated with small impact craters on Earth (see also Huang and Wieczorek, 2012).

A global crustal thickness model of the Moon can be constructed by assuming values for the density of the crust, the density of the mantle, and the mean crustal thickness (see **Section 10.05.5**). The density of the lunar crust can be estimated from either remote sensing data or analyses of the short-wavelength gravity field, whereas the other two free parameters can be determined iteratively by the use of two additional constraints. In practice, the mantle density and mean crustal thickness are varied in order to match the seismically determined crustal thickness and to ensure that the minimum crustal thickness is equal to a chosen value. The most recent interpretations of the Apollo seismic data imply a crustal thickness of either 30 ± 2.5 km (Lognonné et al., 2003) or 38 ± 8 (Khan and Mosegaard, 2002) in the vicinity of the Apollo 12 and 14 landing sites (see also Chenet et al., 2006). When using the constraint that the minimum crustal thickness should be close to zero, as implied by the possible excavation of mantle materials from some impact basins (Yamamoto et al., 2010), the seismic analyses imply an average crustal thickness of either 34 or 43 km (Wieczorek et al., 2013). These average thicknesses imply that the bulk abundance of alumina in the Moon is similar to that of the bulk silicate Earth.

The most notable feature of the global crustal thickness models is the dramatic thinning of the crust beneath the large impact basins. This is a natural consequence of the large quantity of material that is excavated ballistically during the impact process (e.g., Wieczorek and Phillips, 1999), and it is seen that the depth of excavation reaches several tens of kilometers beneath the largest basins. The crustal thickness is close to zero beneath both the Crisium basin on the nearside hemisphere and the Moscoviense basin on the farside hemisphere (see also Ishihara et al., 2009). When combined with the detections of dunite exposures surrounding these two basins, it is likely that these impacts excavated through the entire crust and into the underlying mantle. Despite the great size of the giant South Pole–Aitken basin on the farside, the crust is predicted to be about 20 km thick in its interior. Either the depth of excavation during this basin-forming event was atypically shallow or an impact-generated melt pool differentiated to form a low density crust (Vaughan et al., 2013). The ~1.9 km offset of the Moon's center of mass from its center of figure,

combined with the lateral variations in crustal density as implied by remote sensing data, implies that the farside crust is thicker than the nearside hemisphere by about 8 km.

The majority of the lunar impact basins are characterized by having low elevations, a large central positive free-air gravitational anomaly, a gravity low surrounding the central high, and a gravity high that outlines the basin's topographic rim. Historically, basins with central gravity highs have been referred to as *mascon* basins. The central positive gravitational anomalies are a combination of both uplift of the underlying crust–mantle interface and flexural support of surface mare basalt flows. Based on estimates of the mare basalt thicknesses, which can reach a few kilometers within the central portions of some impact basins, the crust–mantle interface has been shown to be uplifted above its pre-mare isostatic position (e.g., Hikida and Wieczorek, 2007; Neumann et al., 1996; Wieczorek and Phillips, 1999). This hypothesis is supported by the existence of mascon basins that lack evidence of mare volcanism (Konopliv et al., 1998; Zuber et al., 2013b). The surrounding annulus of negative gravity implies that this region of the lithosphere is subisostatic (Andrews-Hanna, 2013), and hydrocode simulations of the basin formation process show that this region of the lithosphere was pushed below its isostatic level during basin formation (Melosh et al., 2013). Subsequent uplift of this subisostatic lithosphere by viscous flow is responsible for uplifting the central portion of the basin above its isostatic level (Andrews-Hanna, 2013; Melosh et al., 2013).

In contrast to the largest impact basins, intermediate-sized craters have negative gravitational anomalies and generally show some form of compensation. Only about 15% of the craters in the Reindler and Arkani-Hamed (2001) study appear to be completely uncompensated or to possess excess negative gravitational anomalies due to crustal brecciation. For these intermediate-sized craters, there does not appear to be any correlation of compensation state with crater age or location.

A few studies have attempted to place constrains on the elastic thickness of the Moon using both gravity and topography data (e.g., Arkani-Hamed, 1998; Crosby and McKenzie, 2005; Sugano and Heki, 2004). Most analyses have concentrated on the mascon basins, but it is often difficult to quantify the validity of the assumptions employed in the loading models. Recent models of mascon formation invoke a two-stage process (basin formation, followed by isostatic adjustment), and it is not trivial to incorporate these aspects into standard analytic flexure models. Furthermore, the thickness of the mare fill is oftentimes not known, and this is critical for fitting the present-day central gravitational anomaly. An alternative method for estimating the elastic thickness is by comparing the location of tectonic features (such as faults and graben) to that predicted by a specified loading model (e.g., Solomon and Head, 1980). Detailed modeling of the Serenitatis basin (Freed et al., 2001) suggests that its elastic thickness was about 25 km when the concentric rilles formed and probably greater than 70 km when the younger compressional ridges formed.

Modeling of the lunar gravity field shows that there are several features related to subsurface density anomalies. As one example, two positive Bouguer gravitational anomalies are found in the vicinity of the Marius Hills volcanic complex (Kiefer, 2013). These positive anomalies most likely represent basaltic intrusions that are more dense than the surrounding crust. If these are modeled as sills, they need to be several kilometers thick and could potentially represent the magma chamber that is responsible for the numerous volcanic domes found in this region. Another example of subsurface density anomalies is linear gravitational anomalies, many of which are several hundred kilometers in length (Andrews-Hanna et al., 2013). These linear anomalies are most visible when plotting horizontal gradients of the gravity tensor (cf. Petrovskaya and Vershkov, 2006) and are plausibly the expression of ancient magmatic dikes that formed when the lunar lithosphere was in a state of extension.

Finally, one curious large-scale feature of Moon is the amplitude of its degree-2 gravity and topography terms. If the Moon were in hydrostatic equilibrium, the amplitude of the C_{20} and C_{22} terms would be directly relatable to the Earth–Moon separation (cf. eqn [21]). The present-day magnitudes of these coefficients, however, are much greater than would be expected for equilibrium at the present time. This has led to the suggestion that the equilibrium shape of the Moon was frozen into the lithosphere when it was closer to Earth early in its orbital evolution (e.g., Jeffreys, 1976; Lambeck and Pullan, 1980). Alternatively, it is possible that this shape is simply a result of large-scale crustal thickness variations or lateral variations in mantle density.

If the observed shape is interpreted as a relict equilibrium shape, then this can be achieved for an Earth–Moon separation of 22 Earth radii with an orbital eccentricity of 0.49 (the current separation and eccentricity are about 60 Earth radii and 0.0549, respectively). If the Moon was in a 3/2 spin–orbit resonance (like Mercury), then alternative solutions exist for an Earth–Moon separation of about 25 Earth radii with eccentricities as low as 0.17. These interpretations are somewhat problematic as the lunar orbit is predicted to have receded beyond this distance in less than ~100 My after the formation of the Earth–Moon system (e.g., Webb, 1982). Furthermore, Ćuk (2011) pointed out that capture into either the synchronous or 3/2 resonance is difficult for the proposed high eccentricities.

10.05.9 Future Developments and Concluding Remarks

The gravitational fields and topography of the terrestrial planets have become increasingly better characterized since the discovery of lunar 'mascons' by Muller and Sjogren in 1968. Whereas the early datasets were quite sparse, the gradual accumulation of data with each successive space mission has given rise to near-global gravity and topography spherical harmonic models. Some of the gravity models now possess spherical harmonic bandwidths greater than 900, and future missions will certainly lead to continued improvements.

Not only has the resolution of the planetary datasets continued to improve with time, but also so have the analysis techniques. Early investigations were often restricted to analyses of individual 1-D line-of-sight gravitational acceleration profiles. As data coverage became more dense, 2-D regional models were developed that were more often than not

analyzed using Cartesian techniques developed for Earth. Because of the small size of some planetary bodies, the assumption of Cartesian geometry is not always justified, and spherical analysis methods have proven to be superior. The full suite of Cartesian gravity–topography analysis techniques has been developed for the sphere, including multitaper spectral analysis, wavelet analysis, the rapid calculation of gravitational anomalies from finite-amplitude topographic relief, and realistic admittance models that take into account surface and subsurface loading. Though the approximation of Cartesian geometry may not incur large errors for some small-scale investigations, it is just as easy to use a spherical-based method that possesses a comparable computational speed.

Much has been learned about the crustal and lithospheric structures of the terrestrial planets, but there is still much to be done. In particular, in hindsight, it is now clear that many gravity–topography admittance and coherence studies have used analysis techniques whose robustness are sometimes difficult to assess. Shortcomings include incorrect application of the multitaper spectral analysis technique, the neglect of either the admittance or correlation function, and the use of a theoretical admittance model that might be an oversimplification of reality. Few studies, even for Earth, have performed these analyses entirely correctly, and one should assess critically each of the elastic thickness estimates that have been published for regions where subsurface loading is important.

It is also important to note that the concept of an elastic lithosphere, which is often used in gravitational analyses, is in actuality a gross oversimplification of reality. Because of the ease of generating a time-invariant flexural profile from a load emplaced on an elastic plate, one would like to hope that the obtained 'effective elastic thickness' has some physical meaning. Though this might be the case for regions where the magnitude of surface and subsurface loading is small and where in-plane forces are absent, it has been demonstrated that the use of a more realistic rheology can yield flexural profiles that sometimes are quite different. Unfortunately, the most realistic EVP models are computationally expensive and are not currently amenable to a robust inversion procedure using gravity and topography as constraints. A simpler elastic–plastic formulation could be used in such an inversion, but this rheological model utilizes assumptions that still might turn out to be too simplistic. Regardless, it would be appropriate to develop an elastic–plastic loading model similar to the elastic model described in **Section 10.05.7** for the sphere. One benefit of such a model is that it would be possible to invert for the regional heat flow. An additional avenue of future research is to compare the locations of surface faulting with those predicted from elastic, elastic–plastic, and EVP models.

Finally, it is worth mentioning that significant improvements to our knowledge of the gravitational fields and topography of the terrestrial planets can be expected in the future. In particular, even though the land-based topography for Earth is now known to high accuracy, there are still gaps near the polar regions that could be filled by data obtained by the orbiting Geoscience Laser Altimeter System (GLAS) laser altimeter (e.g., Abshire et al., 2005; Schutz et al., 2005; Shuman et al., 2006). Data obtained from the terrestrial mission GOCE, which contains a gravity gradiometer, are leading to improved models of the terrestrial gravity field. An area of active research for Earth, but also for the other planets in a more limited sense, is that of measuring and modeling time-variable gravity signatures that are a result of hydrologic processes and tidal deformation.

With respect to the other planets, the topography and gravity field of Mercury are continuing to be characterized by data collected by the MESSENGER spacecraft (Solomon et al., 2001), and these will be supplemented by data that will be collected by the future BepiColombo mission (Spohn et al., 2001). The JUpiter ICy moons Explorer (JUICE) will collect altimetric and gravity data for the icy satellite Ganymede and to a limited extent Europa and Ganymede. Limited gravitational data will also be collected during the end of the Venus Express mission and during the MAVEN mission to Mars.

Acknowledgments

I am indebted to Greg Neumann and Frederik Simons for their numerous discussions relating to the more subtle details of gravity and topography acquisition and analysis. Francis Nimmo, Bruce Bills, Alex Konopliv, David Sandwell, Erwan Mazarico, and Martin Pauer are kindly thanked for their constructive reviews and discussions that helped improve this manuscript. Most figures were created using the Generic Mapping Tools of Wessel and Smith (1991).

10.06.1 Introduction

Planetary magnetism began with the study of the geomagnetic field and is one of the oldest scientific disciplines. Magnetism was both a curiosity and a practical tool for navigation, the subject of myth and superstition as much as scientific study. With the publication of *De Magnete* in 1600, William Gilbert demonstrated that the Earth's magnetic field was like that of a bar magnet. Gilbert's treatise on magnetism established the global nature and dipole geometry of the field and led to an association between magnetism and the interior of planet Earth. Observations of the Earth's magnetic field gathered over time demonstrated that it varies slowly with time. The orientation of the field was observed to execute a long-term or secular drift called polar wander. Later, when accurate measurements of the magnitude of the field could be made, secular variations in the field magnitude were identified. Given the importance of accurate magnetic field maps in navigation, global surveys of the magnetic field were conducted periodically, at first by ships of discovery and commerce and later by specialized magnetic survey ships built to minimize distortion of the magnetic field they sought to measure. In recent times, polar-orbiting, near-Earth satellites such as MAGSAT, Ørsted, CHAMP, SAC-C, and SWARM provided the capability to map the vector magnetic field over the entire surface of Earth in a brief period, to capture a snapshot of the field at each epoch. By studying the magnetic properties of terrestrial rocks, paleomagnetists can extend the history of the geodynamo over timescales of hundreds of millions of years.

Planetary magnetism is also a recent study, born of the space age and a new era of discovery that began in the 1960s with the launch of spacecraft to other bodies. The Sun and stars were known to possess magnetic fields, but one could only speculate on whether the planets and satellites in our solar system were magnetized. The planet Jupiter is an exception; its magnetic field was inferred from the detection of nonthermal radio emissions (Burke and Franklin, 1955) as early as 1955, before the era of planetary exploration. In the decades that followed, the gross characteristics of Jupiter's magnetic field were deduced from variations of the plane of polarization of the emissions or variations in flux density (see, e.g., the review by Berge and Gulkis (1976)). Estimates of the orientation of Jupiter's field (dipole tilt) were more successful than those of its magnitude; the detailed nature of Jupiter's field was established by direct measurement, by spacecraft.

In little more than three decades, spacecraft have visited nearly every large body in the solar system. The first *in situ* observations of the Jovian magnetosphere were obtained by the Pioneer 10 and 11 spacecraft in December 1973 and December 1974, respectively (Acuña and Ness, 1976; Smith et al., 1974, 1975a). The Pioneer 11 spacecraft continued on to make the first observations of Saturn's magnetic field as well (Acuña and Ness, 1980; Smith et al., 1980a,b). Voyagers 1 and 2 followed, passing through the Jovian magnetosphere in March and July of 1979, respectively (Ness et al., 1979a,b). Voyagers 1 and 2 continued onward to Saturn, obtaining additional observations of Saturn's magnetic field in November 1980 and August 1981 (Ness et al., 1981, 1982). Voyager 2 continued on its 'grand tour' of the solar system, with the discovery of the magnetic field of Uranus in January 1986 (Ness et al., 1986) and that of Neptune in August 1989 (Ness et al., 1989). Voyager 2's remarkable tour of the outer solar system was made possible by the celestial alignment of the planets, the syzygy, which occurs every 187 years or so.

Jupiter was visited again in February 1992 by the Ulysses spacecraft en route to the high-latitude heliosphere and again, albeit at great distance, in 2004. Ulysses used a Jupiter gravity assist to escape the ecliptic plane but in so doing passed to within $\sim 6R_j$ (Balogh et al., 1992). Additional observations were obtained by the Galileo orbiter beginning in 1995 (Johnson et al., 1992), but, apart from the deorbit maneuver to send Galileo into Jupiter's atmosphere for planetary protection (of the Galilean satellites), little additional information regarding Jupiter's main field was obtained. Instead, Galileo surprised us with the remarkable discovery of an intrinsic magnetic field of Ganymede (Kivelson et al., 1996) and the induced magnetic fields of Europa and Callisto (Khurana et al., 1998; Zimmer et al., 2000). Today, Cassini orbits Saturn gathering observations throughout the magnetosphere; observations from high-inclination orbits with periapsides near $3R_s$ are just now becoming available. Late in the extended ('Solstice') mission, one set of near-polar orbits will send Cassini through the ring plane near the F ring ($2.3R_s$), and another set ('proximal orbits') will send the spacecraft through the ring plane inside of the entire ring system, just above the cloud tops.

The Mariner 10 spacecraft discovered Mercury's magnetic field in brief flybys in 1974 and 1975 (Ness et al., 1974a, 1975, 1976) and provided the first indication that slowly rotating Venus was not magnetized (Ness et al., 1974b). As of this writing, the MESSENGER (*ME*rcury *S*urface, *S*pace *EN*vironment, *GE*ochemistry, and *R*anging) spacecraft (Gold et al., 2001; Solomon et al., 2001) continues to map the Hermean magnetic field from its vantage point, in an elliptical orbit with periapsis at high northern latitudes. The European Space Agency (ESA)'s BepiColombo mission readies two spacecraft that will orbit Mercury in the near future (Anselmi and Scoon, 2001).

A great many spacecraft visited Mars (Connerney et al., 2005), beginning with the Soviet launch of Mars 1 in 1962, but Mars did not relinquish his secrets until the Mars Global Surveyor (MGS) spacecraft entered orbit about Mars in September of 1997. MGS measurements demonstrated that Mars does not have a global magnetic field of internal origin, but its crust is intensely magnetized (Acuña et al., 1998). So Mars once had an internal magnetic field, for at least as long as it took the crust to acquire remanence. The Mars dynamo has long since disappeared, but the crust retains a magnetic imprint, acquired at least 4 billion years ago, that records at least part of the dynamo's history. The only traditional planet (setting aside the debate on the definition of 'planet') not yet visited by spacecraft is the Pluto–Charon system, which is scheduled for a visit by the New Horizons spacecraft in July 2015. The New Horizons spacecraft is not instrumented to measure magnetic fields, so no direct measurement is possible, but the presence of a magnetic field may be inferred from measurements made by other instruments.

Our knowledge of the magnetic fields of the planets is, in large part, based upon the planetary flybys that occurred decades ago. Mars is the most notable exception, having been mapped thoroughly over the course of more than 9 years by the polar-orbiting MGS spacecraft, operating at a nominal altitude of 400 km (Connerney et al., 2001, 2005). At present, orbiters are operating at both Mercury and Saturn, dramatically extending observational coverage of those planets; elsewhere, the observations are sparse in both space and time, particularly considered in light of the data available for the study of the geomagnetic field. Existing observations are, however, sufficient to describe a diverse group of planetary magnetic fields and provide clues to guide the continued development of dynamo theory. We are also likely to have a much more complete set of observations in the near future, with the Cassini Solstice Mission providing a large number of close-in, polar orbits of Saturn and BepiColombo promising nearly complete global coverage of Mercury. At this time, the Juno spacecraft is en route to Jupiter, perhaps the best target in the solar system for studies of the dynamo. Beginning with orbit insertion in July 2016, Juno will map Jupiter's magnetic field both near and far from a near-polar, elliptical orbit that ducks beneath that planet's intense radiation belts (Bolton et al., 2010).

10.06.2 Tools

A planet with an intrinsic magnetic field stands as an obstacle to the solar wind, the high velocity stream of plasma emanating from the Sun. The interaction of the planetary field and the solar wind forms a multitiered interaction region, often approximated as a set of conic sections. The supersonic solar wind forms a shock upstream of the obstacle (*bow shock*). The slowed solar wind flows around the obstacle within the *magnetosheath*, bounded by the bow shock and the *magnetopause*, often approximated by a paraboloid of revolution about the

planet–Sun line. Within the magnetopause is a region dominated by the planetary field, called the *magnetosphere*, a term introduced by Tom Gold in the postwar era of rocketry that provided access to space in the early 1950s. The magnetospheric magnetic field extends well downstream in the antisunward direction, as if stretched like an archer's bowstring, to form the magnetotail. The observed magnetic field can be regarded as the sum of contributions from several sources, dominated by the planetary dynamo, sometimes referred to as the 'main field.' Other relatively minor sources include currents flowing on the magnetopause and tail currents arising from the solar wind interaction and distributed currents (*ring currents*) due to the coherent motion of charged particles within the magnetosphere. Field-aligned currents, called *Birkeland currents*, flow between the magnetosphere and the planet's electrically conducting ionosphere, particularly during magnetospheric storms, leading to intense auroral displays. All of these currents produce magnetic fields, often relatively small when compared to the planetary field, particularly close to the planet's surface. However, if an accurate model is to be obtained from spatially limited or distant observations, these sources can be a significant source of errors if not modeled.

The planetary field is most often characterized by one of a very few simple models, depending on the application and/or the availability of observations. Simple representations include dipole models of one form or another and a potential field representation as a series of spherical harmonics. External fields, or those arising from currents outside the planet, are often accommodated by explicit models or spherical harmonic methods. The latter approach is useful only in regions free of currents.

10.06.2.1 The Offset Tilted Dipole

Dipole models have found use in the interpretation of magnetic field observations, dating to Gilbert's analysis of the Earth's magnetic field. The dipole is the simplest approximation to a localized source. The vector magnetic field $\mathbf{B}(\mathbf{r})$ of a dipole at the origin is given by

$$\mathbf{B}(\mathbf{r}) = \left[-\frac{\mathbf{m}}{r^3} + \frac{3(\mathbf{m}\cdot\mathbf{r})\mathbf{r}}{r^5}\right]$$

where $\mathbf{m}$ is the magnetic moment in units of $B - r^3$ and $r = |\mathbf{r}|$. The field of a dipole located near the origin is computed by translation of the origin of the coordinate system. Offset tilted dipole (OTD) models are found using forward modeling techniques to compare *in situ* observations to the OTD model field. The dipole offset (x_o, y_o, z_o) is not linearly related to the computed field, so an iterative procedure is often used to find the optimal dipole position (e.g., Smith et al., 1976). Alternatively, one may perform a spherical harmonic analysis (see next section) of degree and order 1 centered upon each of a large number of candidate dipole positions, selecting the offset that minimizes the model residuals. In either case, the result is the OTD that most closely approximates the field measured along the spacecraft trajectory.

The simple OTD representation provides a convenient approximation to the field, particularly useful at larger distances. It is useful in visualizing the gross characteristics of the field, and it is often used to chart the motion of charged particles throughout the magnetosphere. However, the simplicity of the OTD is also a limitation, in that complex field geometries cannot be adequately represented with such a limited parameterization. In general, a dipole representation can be expected to closely approximate the field for radial distances $r \gg a$, where a is a characteristic source dimension. At lesser radial distances, an accurate description of the field requires more flexibility in parameterization, for example, consideration of higher-degree and higher-order moments.

A logical extension of the simple OTD model is one of the many dipoles. The Earth's field has been approximated by adding one or more smaller dipoles to a 'main dipole' and treating the field as a summation over distinct sources; this provides a simple means of introducing an anomaly or departure from dipole geometry. The Earth's field has been approximated by an ensemble of many dipoles located on the surface of a sphere of radius $0.5R_e$, the fluid core radius. In addition to the field generated deep within Earth, induced and remanent magnetizations in the crust can be modeled with another set of dipoles, scattered about a sphere of radius $1.0R_e$ to approximate sources in the crust (Mayhew and Estes, 1983). A similar approach has been taken to model the crustal magnetic field of Mars (Purucker et al., 2000).

10.06.2.2 Spherical Harmonic Models

In the absence of local currents ($\nabla \times \mathbf{B} = 0$), the magnetic field may be expressed as the gradient of a scalar potential $V(\mathbf{B} = -\nabla V)$. It is particularly advantageous to expand the potential V in a series of functions, called spherical harmonics, which are solutions to Laplace's equation in spherical coordinates. This approach, introduced by Gauss in 1839, has been very popular in studies of the geomagnetic field and subsequently those of the planets. The traditional spherical harmonic expansion of V is given by (e.g., Chapman and Bartels, 1940; Langel, 1987)

$$V = a\sum_{n=1}^{\infty}\left\{\left(\frac{r}{a}\right)^n T_n^e + \left(\frac{a}{r}\right)^{n+1} T_n^i\right\}$$

where a is the planet's equatorial radius. The first series in increasing powers of $\mathbf{r}$ represents contributions due to external sources, with

$$T_n^e = \sum_{m=0}^{n}\left\{P_n^m(\cos\theta)\left[G_n^m\cos(m\phi) + H_n^m\sin(m\phi)\right]\right\}$$

The second series in inverse powers of $\mathbf{r}$ represents contributions due to the planetary field or internal sources, with

$$T_n^i = \sum_{m=0}^{n}\left\{P_n^m(\cos\theta)\left[g_n^m\cos(m\phi) + h_n^m\sin(m\phi)\right]\right\}$$

The $P_n^m(\cos\theta)$ are Schmidt quasinormalized associated Legendre functions of degree n and order m, and g_n^m, h_n^m and G_n^m, H_n^m are the internal and external Schmidt coefficients, respectively. These are most often presented in units of Gauss or nanoteslas ($1\ \mathrm{G} = 10^5\ \mathrm{nT}$) for a particular choice of equatorial radius a of the planet. Different values of the equatorial radius have been used and should be noted in the comparison of various field models. The angles θ and ϕ are the polar angles of a spherical coordinate system, θ (colatitude) measured from the axis of rotation and ϕ increasing in the direction of

rotation. The three components of the magnetic field (internal field only) are obtained from the expression for V mentioned previously:

$$B_r = -\frac{\partial V}{\partial r} = \sum_{n=1}^{\infty}\sum_{m=0}^{n}\left\{(n+1)\left(\frac{a}{r}\right)^{n+2}\left[g_n^m\cos(m\phi)+h_n^m\sin(m\phi)\right]P_n^m(\cos\theta)\right\}$$

$$B_\theta = -\frac{\partial V}{r\partial\theta} = -\sum_{n=1}^{\infty}\sum_{m=0}^{n}\left\{\left(\frac{a}{r}\right)^{n+2}\left[g_n^m\cos(m\phi)+h_n^m\sin(m\phi)\right]\frac{\mathrm{d}P_n^m(\cos\theta)}{\mathrm{d}\theta}\right\}$$

$$B_\phi = \frac{-1}{r\sin\theta}\frac{\partial V}{\partial\phi} = \frac{1}{\sin\theta}\sum_{n=1}^{\infty}\sum_{m=0}^{n}\left\{m\left(\frac{a}{r}\right)^{n+2}\left[g_n^m\sin(m\phi)-h_n^m\cos(m\phi)\right]P_n^m(\cos\theta)\right\}$$

The leading terms in the series (through degree 4) may be computed using the Schmidt quasinormalized Legendre functions listed in Table 1.

Table 1 Schmidt quasinormalized Legendre functions

$P_1^0 = (1)\cos\theta$
$P_1^1 = (1)\sin\theta$
$P_1^0 = \left(\frac{3}{2}\right)(\cos^2\theta - 1/3)$
$P_2^1 = \left(3^{1/2}\right)\cos\theta\sin\theta$
$P_2^2 = \left(\frac{3^{1/2}}{2}\right)\sin^2\theta$
$P_3^0 = \left(\frac{5}{2}\right)\cos\theta(\cos^2\theta - 9/15)$
$P_3^1 = \left(\frac{5(3)^{1/2}}{2(2)^{1/2}}\right)\sin\theta(\cos^2\theta - 3/15)$
$P_3^2 = \left(\frac{(3)^{1/2}(5)^{1/2}}{2}\right)\cos\theta\sin^2\theta$
$P_3^3 = \left(\frac{(5)^{1/2}}{2(2)^{1/2}}\right)\sin^3\theta$
$P_4^0 = \left(\frac{35}{8}\right)\left[\cos^4\theta - (30/35)\cos^2\theta + (3/35)\right]$
$P_4^1 = \left(\frac{7(5)^{1/2}}{2(2)^{1/2}}\right)\cos\theta\sin\theta(\cos^2\theta - 3/7)$
$P_4^2 = \left(\frac{7(5)^{1/2}}{4}\right)\sin^2\theta(\cos^2\theta - 1/7)$
$P_4^3 = \left(\frac{(7)^{1/2}(5)^{1/2}}{2(2)^{1/2}}\right)\cos\theta\sin^3\theta$
$P_4^4 = \left(\frac{(7)^{1/2}(5)^{1/2}}{8}\right)\sin^4\theta$

The leading term (in parentheses) converts the functions from Gaussian normalization, convenient for recursive computations, to Schmidt quasinormalized form.

Observations are often rendered in a west longitude system, in which the longitude of a stationary observer increases in time as the planet rotates. West longitudes are simply related to the angle ϕ by $\lambda = 360 - \phi$. Longitudes for the terrestrial planets may be assigned by reference to surface features. For the outer planets, the rotation period is inferred from observations of episodic radio emissions, which, by assumption, are locked in phase with the rotation of the planet's magnetic field and hence the electrically conducting deep interior of the planet. For these planets, longitudes must be assigned with knowledge of the rotation rate and time. For Jupiter, observation of high-frequency radio emission (penetrating the Earth's ionosphere) over several decades led to an accurate determination of the planet's rotation period, although one must be cognizant of the occasional update (e.g., λ_{III} (1957) vs. λ_{III} (1965)). These two systems result in significantly different longitudes when observations of the Pioneer era are compared with those of the Voyager era, so one must be careful to transform earlier results to a current coordinate system. A detailed description of Jovian coordinate systems is given by Dessler (1983). For Saturn, Uranus, and Neptune, the rotation periods and longitude system in current use are derived from Voyager observations of radio emissions (Desch and Kaiser, 1981; Desch et al., 1986; Warwick et al., 1989). In practice, the use of a radio-derived rotation period satisfies the need for a planet-fixed coordinate system for fluid planets, but exceptions (e.g., Saturn) do exist.

The expansion in increasing powers of r, representing external fields, is often truncated at $n = N_{\max} = 1$ corresponding to a uniform external field due to distant magnetopause and tail currents, that is, sources well beyond the region of interest. No potential field can represent the field of local currents, so in practice, the external expansion is often truncated at $N_{\max} = 1$ and local currents are modeled with the aid of explicit models. The dominant contribution from local currents may be described as a large-scale equatorial current system (Connerney et al., 1981). Field-aligned or Birkeland currents may also play a role in addition to induction effects but thus far have not been included in such analyses, excepting those of Earth (e.g., Backus, 1986; Sabaka et al., 2002). It is very important to adequately treat the fields of local currents, because even small errors accumulating along the spacecraft trajectory can lead to rather large errors in the spherical harmonic coefficients deduced from observations. Fields produced by external current systems vary over relatively short timescales (e.g., in response to variations in the solar wind ram pressure on the magnetopause), further complicating modeling efforts.

The maximum degree and order required of the internal field expansion depends on the complexity of the field measured. In usual practice, the series mentioned earlier is truncated at a maximum degree $N_{\max}$, where $N_{\max}$ is large enough to follow variations in the field at the orbital altitude of the measurement. The number of free parameters grows rapidly with increasing $N_{\max}$, as $n_p = (N_{\max}+1)^2 - 1$. If the observations are well distributed on a sphere, the spherical harmonics do not covary, and the coefficients obtained are independent of the truncation of the series. However, if the observations are poorly distributed or sparse, as is often the case for a planetary flyby, the usual spherical harmonics covary, so it is advisable to construct new orthogonal basis functions. Furthermore, if an

arbitrarily small choice of N_{max} is imposed upon the model in order to obtain a manageable linear system, large errors in low-degree and low-order terms will result from the neglect of higher-order terms. To address these problems, Connerney (1981) introduced a method of analysis based on the singular value decomposition (SVD) of Lanczos. The method (Lanczos, 1971) involves the construction of partial solutions to the generalized linear inverse problem to obtain estimates of those parameters that are constrained by the observations. The model parameters that are not constrained by the data are readily identified and exploited in characterization of model nonuniqueness. One advantage of this approach is that the physical model of the planetary field (expansion to degree N_{max}) does not depend on the completeness or extent of the available observations. Partial solutions, and estimates of the model parameters that result, may be interpreted within the context of the 'resolution matrix' for the particular solution (see Connerney, 1981; Connerney et al., 1991). The close flyby of Neptune in 1989 serves to illustrate this concept well.

10.06.3 Terrestrial Planets

10.06.3.1 Mercury

Mercury, the smallest ($R_m = 2439$ km) and least massive ($M_m = 0.056 M_e$) planet in the solar system, occupies the pole position in its race about the Sun, with a semimajor axis of 0.39 AU. Due to its large orbital eccentricity (0.206), in one orbit about the Sun (88 days), its orbital radius varies from 0.31 to 0.47 AU. It is locked in a spin–orbit resonance (Goldreich and Peale, 1966; Pettengill and Dyce, 1965) rotating once every 58.65 days or three times every two orbital periods. It is difficult to observe from Earth, due to its proximity to the Sun, and little was known about Mercury prior to observation by spacecraft on 29 March 1974, the first of the three encounters with the Mariner 10 spacecraft. Discovery of the intrinsic magnetic field of Mercury was a bit surprising since it was widely assumed that a body as small as Mercury would have completely solidified, ruling out generation of a magnetic field by dynamo action. The Mariner 10 observations of Mercury provided the only *in situ* observations obtained in the first four decades of space exploration. As this chapter is being written, the MESSENGER spacecraft (Gold et al., 2001; Solomon et al., 2001) is orbiting Mercury, in part to better understand the internal magnetic field and its origin. MESSENGER entered orbit in March 2011, after a series of flybys of Earth (August 2005), Venus (October 2006 and June 2007), and Mercury (three flybys: January 2008, October 2008, and September, 2009). A more ambitious mission to Mercury, 'BepiColombo,' is in development by the ESA and the Institute of Space and Astronautical Science (ISAS) in Japan for launch in the not too distant future (Anselmi and Scoon, 2001).

10.06.3.1.1 Observations

Mariner 10, known prelaunch as the Mariner Venus–Mercury spacecraft, was launched on 3 November 1973. The spacecraft used a close flyby of Venus on 5 February 1974 (for gravity assist) to achieve three close encounters with Mercury (29 March 1974, 21 September 1974, and 16 March 1975) before it exhausted its expendables. The orbital period of Mariner 10 after the Venus gravity assist was 176 days, very nearly commensurate with Mercury's orbital (and rotation) period, providing three very similar close encounters. Each time the spacecraft approached the planet from a local time of ~19.00 h and departed near 07.00 h. Given the brevity of these flyby encounters, the relatively slow planetary rotation rate, and the orbital commensurabilities, each encounter approximates a shot past a stationary object, the major difference being the altitude and subspacecraft latitude of the point of closest approach. The first and third of these encounters (M10-I and M10-III) provided observations within the Hermean magnetosphere (Figure 1); the second was targeted well above the sunlit hemisphere and beyond the reach of the Hermean magnetosphere in the upstream direction of the solar wind.

Mariner 10's first flyby was relatively close, as planetary flybys go, with a periapsis of $1.29 R_m$ over the darkened hemisphere (antisunward direction), passing from dusk to dawn behind the planet as viewed from the Sun. Mariner 10 traveled from bow shock (inbound) to bow shock (outbound) in a mere 33 min, 17 of which were spent within the confines of a Hermean magnetosphere (Figure 2). These observations are best understood in terms of the field external to the planet, even at such a close distance. The field increased in magnitude from about 45 nT just inside the magnetopause to ~100 nT, all the while maintaining the antisunward orientation characteristic of a planetary magnetotail. As Mariner 10 crossed the equator plane, the field decreased in magnitude precipitously, as if crossing a current sheet, after which it was much smaller in magnitude and chaotic, lacking the smooth variation and consistent orientation that characterized the inbound pass. These observations indicated that Mariner 10 passed through a small magnetosphere, sized just large enough to contain the solid body of the planet under nominal solar wind conditions (Ness et al., 1975). To form such a magnetosphere, Mercury must

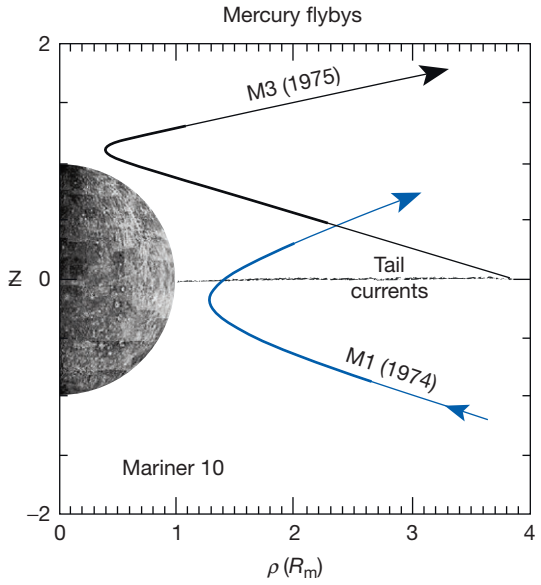

Figure 1 Mariner 10 trajectory in Mercury-centered cylindrical coordinates for the first (M1) and third (M3) encounters. The spacecraft distance from the equator (z) as a function of distance from the z-axis (ρ) is given in units of Mercury radius. The part of the trajectory within the Hermean magnetosphere is indicated by the thick line segment.

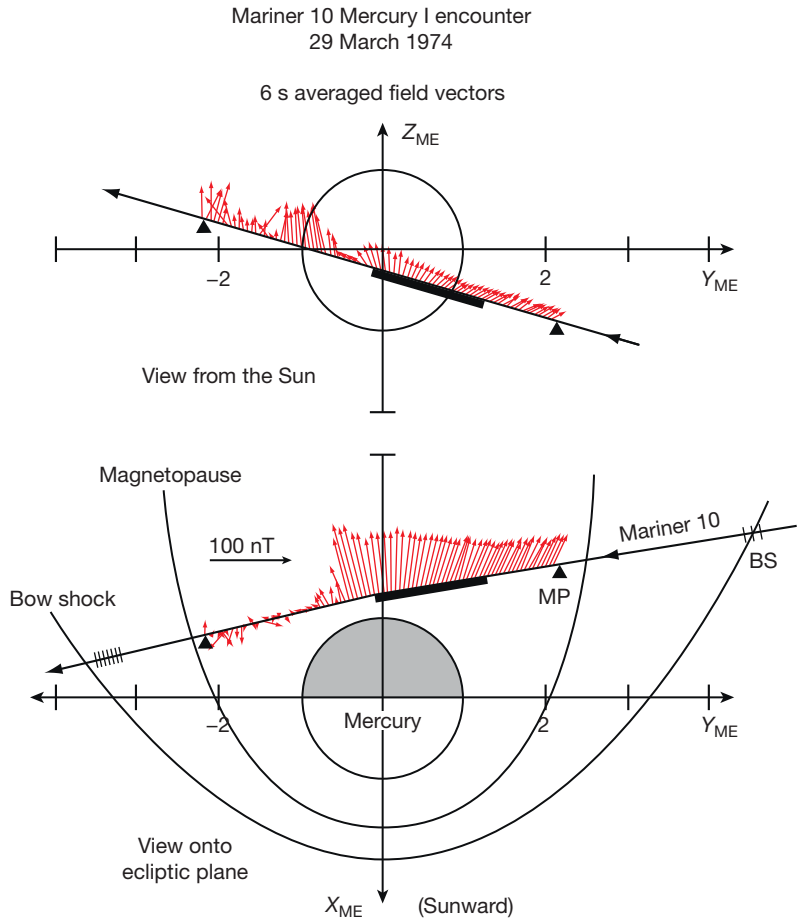

Figure 2 M1 encounter trajectory and magnetic field observations in Mercury ecliptic coordinates, viewed from the Sun (top) and viewed along Mercury's rotation axis (bottom). The vector magnetic field observed along the Mariner 10 trajectory is illustrated by vector projection onto the *z*–*y* (top) and *x*–*y* (bottom) planes; vectors originate at the spacecraft position in ME coordinates at the time of observation. Observed bow shock (BS) and magnetopause (MP) positions are shown along with scaled nominal bow shock and magnetopause boundaries.

have an internal magnetic field, albeit one with a modest dipole magnitude.

Mariner 10's second flyby was upstream of Mercury in the solar wind and too distant to penetrate the small Hermean magnetosphere. However, the third flyby was targeted to pass closely over the northern pole (Figure 3), in an effort to gather measurements optimized for characterization of the Hermean field. During the spacecraft's brief traversal of the magnetosphere (14 min), the field increased from about 20 nT to a maximum of 402 nT observed just after closest approach at $1.14R_m$ radial distance ($1R_m = 2439$ km). The approximate $1/r^3$ dependence of the observed field on spacecraft radial distance establishes the internal origin of the field, and initial analysis (Ness et al., 1976) suggested a dipole moment of ~ 342 nT-R_m^3, aligned with the $-Z$-axis (normal to the Hermean orbital plane).

The three MESSENGER flybys (M1, M2, and M3) prior to orbit insertion were quite similar to the Mariner 10's first flyby (M10-I), in that all three passed through Mercury's shadow at low latitude, sampling the internal field near the innermost extent of the cross tail current sheet (Anderson et al., 2010). The maximum total field measured during the M1 and M2 passes was ~160 nT, a magnitude that is comparable to the ~100 nT of external field produced by tail and magnetopause currents that result from the solar wind interaction (Korth et al., 2004). The third MESSENGER flyby was interrupted by a spacecraft safe mode entry near closest approach, and instruments were 'safed,' or powered off, for a brief period of time before nominal operations were restored.

MESSENGER entered orbit about Mercury on 17 March 2011 and became the first spacecraft to orbit the innermost terrestrial planet of our solar system. MESSENGER initially entered a highly elliptical, near-polar (82°–84° orbit inclination) orbit with a period of about 12 h (Figure 4); these orbits sample all local times as Mercury orbits the Sun, with closest approach altitudes ranging from 200 to 500 km at high (60°–74°) northern latitudes. After an Earth year in this orbit, the extended mission began with a pair of maneuvers (16 and 20 April 2012) that reduced the orbital period to 8 h. As of this writing, MESSENGER has completed over 2600 such orbits.

10.06.3.1.2 Models

Two fundamental issues arise in modeling the Hermean magnetic field. The first is a simple consequence of the relative

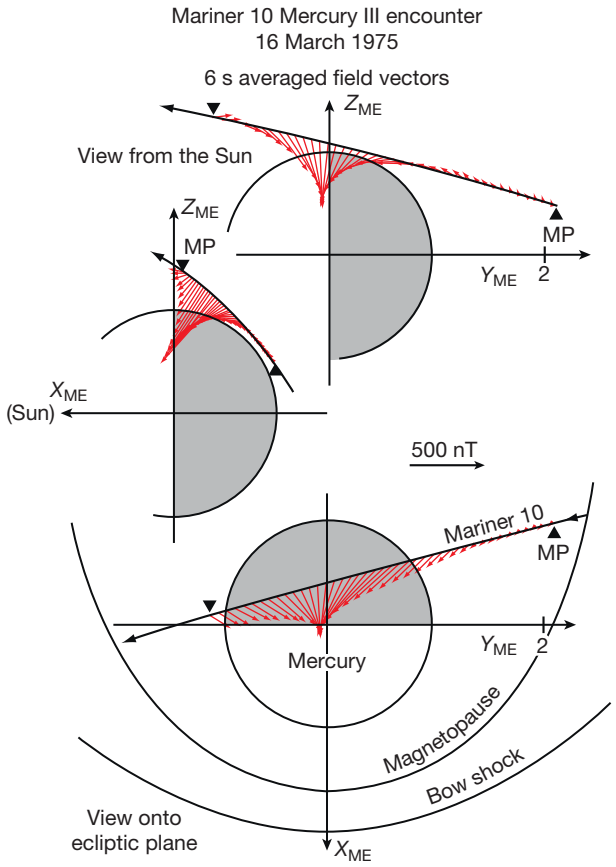

Figure 3 M3 encounter trajectory and magnetic field observations in Mercury ecliptic coordinates, viewed from the Sun (top) and viewed along Mercury's rotation axis (bottom). The vector magnetic field observed along the Mariner 10 trajectory is illustrated by vector projection onto the *z*–*y* (top), *x*–*z* (middle), and *x*–*y* (bottom) planes; vectors originate at the spacecraft position in ME coordinates at the time of observation. Observed magnetopause (MP) positions are shown along with scaled nominal bow shock and magnetopause boundaries.

weakness of the field, with a dipole moment only 0.05% that of Earth's; the second is a more subtle consequence of the distribution of observations collected by spacecraft in the immediate vicinity of the planet. With such a weak internal field, the planet occupies much of its magnetosphere, and the contribution of magnetospheric currents – primarily magnetopause currents and cross tail currents – is relatively large, time-variable, and difficult to model with great accuracy. Thus, models of Mercury's magnetic field fall largely into two groups, distinguished by their treatment of external fields. The first group of models used a spherical harmonic expansion for both internal and external fields and were limited to the dipole ($n=1$) terms for internal fields. Since these are potential field models, they are restricted to the region in which no currents flow, so they may be applied, for example, within only one lobe of the tail. Initial analyses used the first inbound Mariner 10 observations through to the tail current sheet crossing, while later analyses benefited from the Mariner 3 observations obtained crossing the pole. The latter are better suited to internal field estimation by virtue of improved signal to noise (magnitude relative to external fields). These are listed in **Table 2**.

Another set of models were obtained using a spherical harmonic expansion for the internal field, augmented by explicit models of the external field. These included more detailed models of the fields due to magnetopause and tail currents, the latter being of great importance in interpretation of the first Mariner 10 encounter (M10-I) and the MESSENGER M1 and M2 close flybys. An explicit model of the external field allows one to extend analyses through regions of local currents (e.g., tail current sheet), accommodating nonpotential fields more readily. A number of these models (Bergan and Engle, 1981; Jackson and Beard, 1977; Ng and Beard, 1979; Whang, 1977) were applied to M10 observations and allowed for the possibility of internal field through degree 2 or 3 but only in the zonal harmonic ($m=0$) coefficient, for example, g_2^0 and g_3^0. Models allowing for axisymmetric quadrupole ($n=2$) or octupole ($n=3$) terms are characterized by a reduced dipole magnitude, relative to models allowing dipole terms only. This

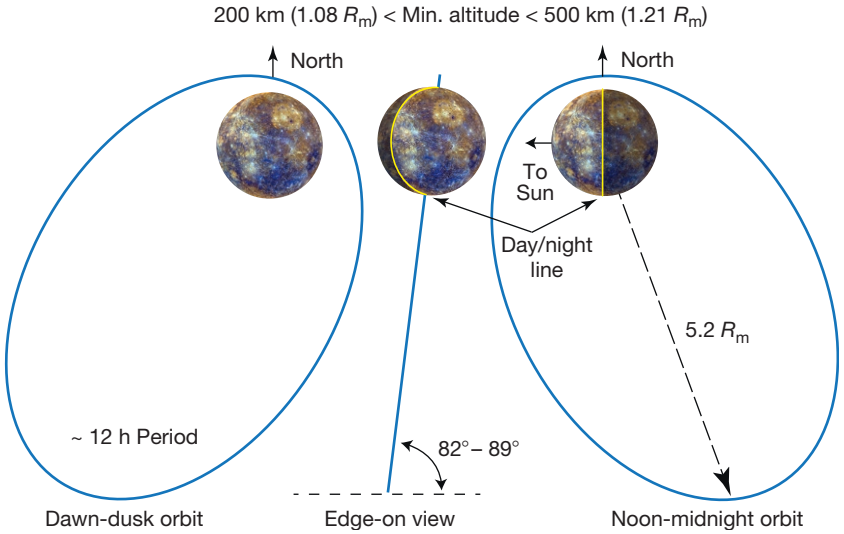

Figure 4 MESSENGER orbits about Mercury slowly evolve in local time (dawn–dusk at left; noon–midnight at right) as Mercury orbits the Sun. Closest approach to Mercury at altitudes of ~200 to ~500 km occurs at high northern latitudes (60°–74°).

Table 2 Mercury magnetic field models

Model[a]	g_1^0*(nT-*R_m^3*)*	*Data*	*Reference*	*Comments*
I1	227	I(1/2)	Ness et al. (1974a,b)	No external field modeled
I1E2	350	I(1/2)	Ness et al. (1975)	External field model improves internal fit
I1E1	342 ± 15	III	Ness et al. (1976)	III data better suited for modeling internal field
I1E1	330 ± 18	III	Ness (1979a,b)	III subsets modeled to estimate errors

[a]I1 denotes internal expansion of degree/order 1; E*n* denotes external field expansion of degree/order *n*.

applies to all such models, regardless of author or method of analysis or even the details of the explicit models chosen to represent fields of external origin. This curious effect was shown to be related to model nonuniqueness, a consequence of the limited spatial extent of the data (Connerney and Ness, 1988). With spatially limited observations, the internal field parameters and the external field parameters covary, in a predictable way, and cannot be uniquely determined, lacking additional information. Thus, following the Mariner 10 encounters, there was no evidence either for or against a nonzero axisymmetric quadrupole or octupole. Either model an offset dipole or a simple dipole (e.g., Ness et al., 1979a,b) provides an acceptable, if not entirely satisfactory, description of Mercury's internal magnetic field. This model nonuniqueness could only be resolved with additional close-in observations, preferably distributed more uniformly about the planet and in particular above the southern pole. The internal field is just sufficient to keep the dayside magnetopause above the planet's surface under nominal solar wind conditions (**Figure 5**).

Initial analyses of the MESSENGER observations used the M1 and M2 flybys, in combination with Mariner 10 observations, and a variety of explicit models of the external field, to obtain qualitatively similar results. Anderson et al. (2008, 2010) and Uno et al. (2009) found a number of dipole representations with moments ranging from 240 to 270 nT-R_m^3 and dipole tilts of 5°–12° from the rotation axis, as well as (northward) offset dipole models that fit equally well with reduced dipole moment and negligible tilt. Alexeev et al. (2010) modeled the Mariner 10 and MESSENGER flybys, fitting an elaborate external field model to each, individually, concluding that Mercury's internal field is best represented by an axial dipole, with a moment of 196 nT-R_m^3, offset from the planet's center by 405 km ($0.17R_m$) to the north. This result is rather similar to the Mariner 10 models (Bergan and Engle, 1981; Ng and Beard, 1979) characterized by an aligned dipole (with a moment of 180–207 nT-R_m^3) offset by 0.17–0.19R_m northward along the *z*-axis.

10.06.3.1.3 Discussion

MESSENGER's orbital phase has thus far provided a wealth of additional observations, well distributed in longitude and local time, but close-in observations are still limited to high northern latitudes. Thus, the nonuniqueness inherent in the limited spatial distribution of observations – the covariability of the main dipole (g_1^0) term, northward offset or g_2^0 term, and the external field – described by Connerney and Ness (1988) and Korth et al. (2004) remains extremely challenging. Only by constraining, independently, the northward offset of the dipole using relatively distant observations of the location of the magnetic equator (Anderson et al., 2011, 2012; Johnson et al., 2012) has it been possible to deduce the magnitude of the dipole (~190 nT-R_m^3, corresponding to a northward dipole offset of ~480 km) from a few Mercury years of MESSENGER orbital observations. This internal field model, along with a prescribed paraboloid magnetospheric model (Alexeev et al., 2010), fits selected MESSENGER orbits very well (Johnson et al., 2012). However, the uniqueness of this particular solution has yet to be demonstrated. The (averaged) magnetic equator locations critical to constraining the dipole offset are available at essentially two radial distances (~1.4 and ~2.5R_m) determined by MESSENGER's fixed orbit; the innermost magnetic equator observations are available at most local times but in close proximity to the magnetopause. The more distant observations are necessarily confined to a narrow range of local times (near midnight). The magnetotail current sheet geometry may be more complex than assumed, near the magnetopause, and somewhat warped across and down the tail, as is observed at Earth (Fairfield, 1980; Gosling et al., 1986; Zhang et al., 2006). Given that the external field contributes up to 40% or 50% of the field measured (Anderson et al., 2010; Johnson et al., 2012), one must be very confident in

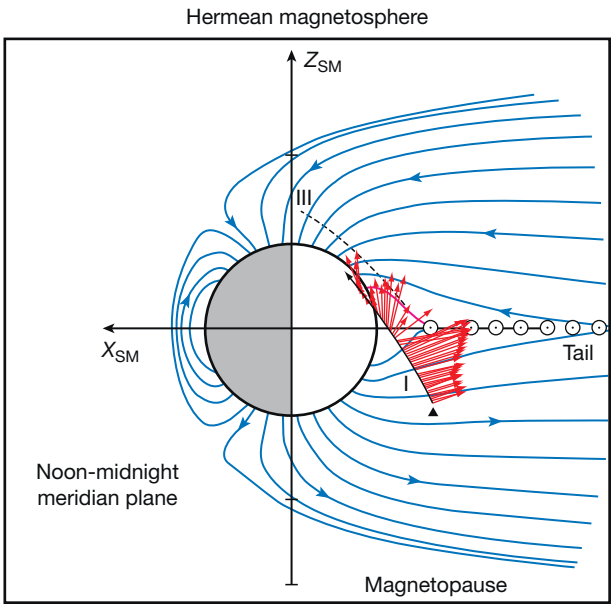

Figure 5 Magnetic field lines of a model Hermean magnetosphere (blue) in meridian plane projection (*x*–*z* plane) compared with the vector magnetic field observed along the M1 passage through the magnetotail.

knowledge of the external field in order to narrow the range of uncertainty in the internal field parameters (especially the *zonal* harmonics). The $g_1^0 - g_2^0$ covariability may only really be resolved satisfactorily after BepiColombo's well-distributed orbital measurements (**Figure 6**) are available (Scuffham et al., 2006). There remains the intriguing possibility of detecting, and characterizing, a putative crustal magnetic anomaly with the many close passes afforded by either MESSENGER or BepiColombo, but as yet no unambiguous evidence for such has emerged (Purucker et al., 2009).

10.06.3.2 Venus

Venus is similar to Earth in size ($R_v = 6051$ km), mass ($M_v = 0.815 M_e$), and density, and probably composition as well. Venus orbits the Sun once every 225 days at a mean orbital radius of 0.723 AU. Proximity to Earth has invited a relatively large number of missions, particularly in the early decades of space exploration (Colin, 1983; Russell and Vaisberg, 1983). However, unlike Earth, Venus has no measureable internal magnetic field; spacecraft have detected only weak magnetic fields associated with the solar wind interaction (Russell and Vaisberg, 1983). Venus also rotates very slowly, with a period of 243 days. The relatively slow rotation in itself does not explain the lack of a dynamo, as it is easily enough to make Coriolis forces dynamically important (Stevenson, 2003).

10.06.3.2.1 Observations

The first measurements of the magnetic field near Venus were obtained in December 1962, by the Mariner 2 spacecraft, on a flyby trajectory with a closest approach of 6.6 planet radii. Magnetic field measurements obtained by the triaxial fluxgate magnetometer (FGM) aboard Mariner 2 provided no evidence of an intrinsic planetary field (Smith et al., 1963, 1965a) at this distance. Venus could not have an internal magnetic field with a moment exceeding 0.05 that of the Earth.

The 1960s and 1970s saw the arrival of the Venera 4 (1967) and Venera 6 (1969) entry probes and the Mariner 5 (1967) and Mariner 10 (1974) spacecraft on flyby trajectories with close approach distances of 1.7 and $1.96 R_v$. These were followed by the Venera 9 and 10 orbiters in 1975 and the Pioneer Venus Orbiter (PVO) in 1978. The Veneras were placed in highly elliptical orbits with an orbital period of ~48 h, periapsis at 1545 and 1665 km altitude, respectively, and apoapsides of $\sim 18.5 R_v$. Throughout this period, the existence of an intrinsic magnetic field was debated (see Russell and Vaisberg, 1983) amid ever-decreasing estimates, or upper limits, on the Venus dipole moment. The PVO was placed in a highly elliptical orbit with an orbital period of 24 h, periapsis at 140–170 km altitude, and apoapsis at $\sim 12 R_v$. This orbit geometry afforded observation of, and a better understanding of, the interaction of the solar wind with a planetary atmosphere. These observations led to an upper limit on the Venus dipole moment of 4×10^{-5} that of Earth's (Russell et al., 1980), which was reduced further (to $\sim 1 \times 10^{-5} M_e$) by a more exhaustive analysis (Phillips and Russell, 1987) that also demonstrated a lack of evidence for magnetic fields associated with crustal remanence. The Venus Express spacecraft, in a highly elliptical polar orbit about Venus since April 2006, will not likely alter conclusions regarding the internal magnetic field of Venus (Zhang et al., 2006).

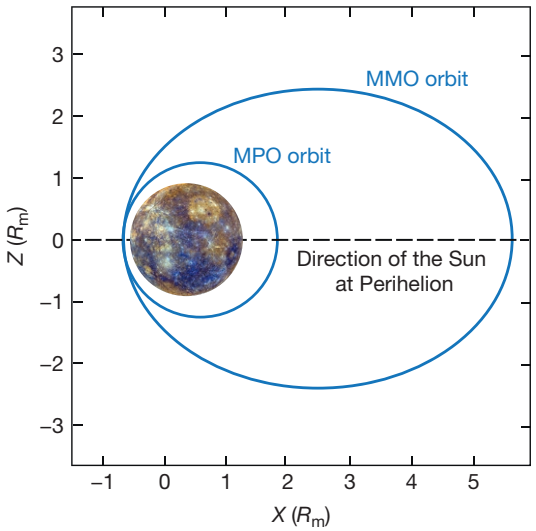

Figure 6 Coplanar polar orbits of the BepiColombo mission spacecraft. The three axis stabilized Mercury Planetary Orbiter (MPO) will complete an orbit about Mercury in about 2.3 h, while the Mercury Magnetospheric Orbiter (MMO), a spin-stabilized spacecraft, will have an orbit period of about 9.3 h; both spacecraft will have a closest approach altitude of 400 km. Launch is scheduled in July 2016.

10.06.3.2.2 Discussion

One concludes that Venus does not currently have an active dynamo; at present, little can be said of the possibility that Venus once sustained a dynamo. One would like to understand why this Earth-like planet does not have an active dynamo, and there are many possibilities (Spohn, 1991; Stevenson, 2003). The favored explanation is that sufficient convection in the fluid outer core is lacking at present, owing perhaps to the inefficiency of heat transport (relative to Earth, where plate tectonics helps cool the core). More specifically, the lack of a present-day dynamo may be the result of a cessation of plate tectonics on Venus (Nimmo, 2002), as has been proposed for Mars (Nimmo and Stevenson, 2000).

10.06.3.3 Mars

Mars is about half the size ($R_m = 3394$ km) of Earth and much less massive ($M_m = 0.108 M_e$). Mars resides at a mean orbital distance of 1.52 AU, orbiting the Sun once in 687 days. It has also been an attractive target for planetary exploration, playing host to more than 30 attempted missions since 1960 (Connerney et al., 2004). At present, one of the indefatigable Mars Exploration Rovers continues to explore the surface after more than 10 years of service (Crisp et al., 2003). The MGS spacecraft (Albee et al., 1998) fell silent in 2006 after more than 9 years in orbit, and Mars Odyssey (Saunders et al., 2004), Mars Express (Chicarro et al., 2004), and the Mars Reconnaissance Orbiter (Graf et al., 2005) all continue to acquire observations from orbit. The Mars Science Laboratory (MSL) was delivered to the surface in August 2012 to begin its search for environmental conditions suitable for past or present microbial life, and the MAVEN spacecraft is en route to Mars (arrival

21 September 2014) to begin a year-long study of the Mars atmosphere. It is the most impressive armada of spacecraft ever assembled for planetary exploration, although only one currently active vehicle – the MAVEN spacecraft – is instrumented to measure magnetic fields.

10.06.3.3.1 Observations

After five unsuccessful attempts (four by the USSR and one by the United States), Mariner 4 became the first mission to return data from Mars on 15 July 1965. Mariner 4's flyby trajectory brought the spacecraft to within $4R_m$ of the planet, from which vantage point it observed the near-Mars environment. The magnetic field was indistinguishable from the interplanetary environment; no bow shock, no magnetopause, and no magnetosphere were observed. If Mars had an intrinsic magnetic field, it had to be very small in magnitude, $<3\times10^{-4}M_e$ (M_e, the magnetic dipole moment of Earth, is 8×10^{25} G cm^3), to remain unseen (Smith et al., 1965b). This upper limit is equivalent to an equatorial surface field of 100 nT, well less than Earth's (30 000 nT) but not so much less than the as yet undiscovered magnetic field of Mercury (330 nT).

In the following three decades, numerous spacecraft visited Mars, but no spacecraft, probe, or lander instrumented to measure magnetic fields would pass close enough to the surface to establish the presence of an intrinsic magnetic field. The US missions following Mariner 4 and Mariner 9 (1971) and Viking 1 and Viking 2 (1975) were not instrumented to measure magnetic fields. Additional magnetic field observations were obtained by the Soviet Mars 2, 3, and 5 spacecraft (Ness, 1979a; Russell, 1978a, 1979) in the early 1970s and the Soviet Phobos 2 mission in 1988. These observations fueled a great deal of debate regarding the existence of a putative Mars dipole (with equatorial surface field in the range 20–65 nT), but no convincing evidence of an intrinsic field was found (Riedler et al., 1989).

Thus, it was the MGS spacecraft (Albee et al., 1998), launched in 1996 as a (partial) replacement for the unsuccessful Mars Observer, that provided the first unambiguous detection of the intrinsic magnetic field of Mars. On 11 September 1997, the MGS spacecraft was inserted into a highly elliptical polar orbit from which it would transition to a circular polar mapping orbit (nominal 400 km altitude) via a series of aerobraking maneuvers (Albee et al., 1998). Aerobraking uses atmospheric drag to slow the spacecraft, gradually reducing apoapsis by repeated passage through the atmosphere; trim maneuvers are used to raise or lower the altitude at closest approach (periapsis) to obtain the desired drag. Each aerobraking pass brought the spacecraft over the surface of Mars, to altitudes <100 km, about as close to the surface as any orbiting platform can achieve. During each aerobraking pass, the MGS magnetometer/electron reflectometer (MAG–ER) investigation (Acuña et al., 1992) acquired measurements of the vector magnetic field along the orbit track at varying altitude above the surface.

Periapsis pass 6 (day 264, 1997) provided a wealth of scientific insight in a few minutes time: lacking a significant field of global scale, Mars has no active dynamo, but must have had one in the past, when the crust acquired intense remanent magnetization (Acuña et al., 1998). These observations are illustrated in Figure 7, showing the spacecraft trajectory and

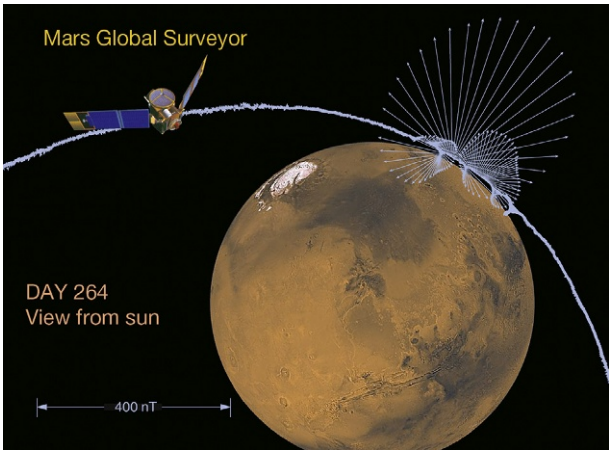

Figure 7 Mars Global Surveyor trajectory and magnetic field observations in an orbit plane projection for day 264, 1997. The vector magnetic field observed along the MGS trajectory is illustrated by vector projection onto the orbit plane; vectors originate at the spacecraft position at the time of observation. Reproduced from Connerney JEP, Acuña MH, Ness NF, Spohn T, and Schubert G (2004) Mars crustal magnetism. *Space Science Reviews* 111(1–2): 1–32.

vector magnetic field measured at 3 s intervals along the trajectory. From this image, one can see that the intrinsic field is not global in scale, as it would necessarily be if it were generated deep within the planet by dynamo action. Instead, the field is localized to a small part of the trajectory, with a characteristic length scale comparable to the altitude of observation. This is the signature of a strong and localized magnetic source in the crust of Mars, just beneath the spacecraft orbit track. This particular source produces a field of nearly 400 nT at ~110 km altitude, requiring a very large volume of intensely magnetized material, with a moment of $\sim1.6\times10^{16}$ A m^2 (Acuña et al., 1998).

The MAG–ER investigation on MGS acquired magnetic field observations on over 1000 aerobraking passes during the transition to mapping orbit. On each such pass, the crustal field was sampled at low altitude along a limited ground track centered on the latitude and longitude of periapsis and extending approximately ±25° in latitude north and south of closest approach. Periapsis passes were distributed more or less randomly in longitude, as the orbit period was shortened by aerobraking, and over the course of aerobraking, the latitude of periapsis slowly evolved from ~30° north latitude to ~87° south. Thus, MGS was able to sample crustal fields over nearly the entire planet surface, which led to a map of the global distribution of magnetic sources in the Mars crust (Acuña et al., 1999). This map, reproduced here (Figure 8), is compiled by color coding, the (largely north–south) subspacecraft trajectory using the radial magnetic field component measured at that latitude and longitude. No correction for spacecraft altitude, which varies along the track from periapsis (~100 km) to 200 km, was attempted in this presentation. The most significant magnetic sources are distributed nonrandomly, largely confined to the older, heavily cratered terrain south of the dichotomy boundary; vast regions of the smooth northern plains are relatively nonmagnetic, as are the Argyre and Hellas impact craters and prominent volcanic

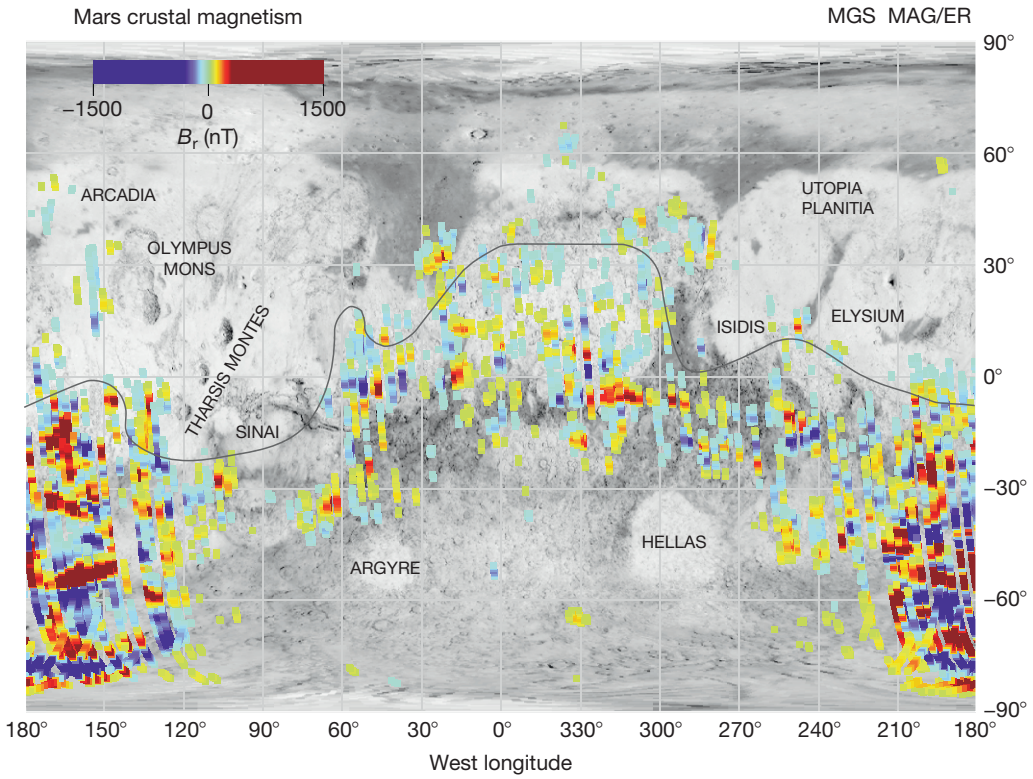

Figure 8 Global distribution of the most intense magnetic sources in the Mars crust. Magnitude of the radial magnetic field measured during the Mars Global Surveyor aerobraking passes below 200 km altitude (to ~100 km minimum altitude). Most intense sources are found in the heavily cratered southern highlands, south of and near the dichotomy boundary (thin line). Reproduced from Acuña MH, Connerney JEP, Ness NF, et al. (1999) Global distribution of crustal magnetism discovered by the Mars Global Surveyor MAG/ER experiment. *Science* 284: 790–793.

edifices (Acuña et al., 1999). This led Acuña et al. to conclude that the Mars dynamo likely operated for a brief (few 100 My) period following accretion (~4.5 Ga) and had ceased to operate by the time of the late large impacts, about 3.9 Ga. More comprehensive studies of the magnetic fields above impact basins arrived at essentially the same conclusion (Lillis et al., 2008, 2013).

In March of 1999, MGS completed the transition to circular, polar mapping orbit with nominal altitude of 400 km, from which it would begin its mapping mission. The orbit is fixed in local time (2 a.m.–2 p.m.), and subsequent orbits cross the equator 28.6° westward of the previous orbit. Each 'mapping cycle' of 28 days duration provides uniform sampling of the globe with track-to-track separation of about 1° of longitude (59 km) at the equator. Subsequent mapping cycles increase the density of ground tracks, providing complete global coverage with track-to-track spacing of 3 km at the end of 1 Mars year (687 days). MGS passes over the same location on Mars many times; thus, the vector magnetic field at satellite altitude can be mapped with extraordinary signal to noise (Connerney et al., 2001). This particular map was compiled with observations obtained over the nightside, where time-variable fields due to the solar wind interaction are minimized, to improve the signal fidelity of the crustal field. The crustal field at mapping altitude reaches a maximum of ~220 nT over the intensely magnetized southern highlands. This and other compilations of MGS observations are available online at http://mgs-mager.gsfc.nasa.gov.

A much improved map of the field produced by crustal sources was obtained by using a more effective means to remove residual external fields (Connerney et al., 2005). This map (**Figure 9**) is a 360×180 pixel 'image' of the filtered radial magnetic field, each pixel representing the median value in a $1° \times 1°$ latitude–longitude bin. This map represents the change in radial field, or $\triangle B_r$, in nanotesla per degree latitude, as the spacecraft moves north to south over the darkened hemisphere. The map is superposed upon a Mars Orbiter Laser Altimeter (MOLA) shaded topography map (Smith et al., 1999), which appears in any pixel for which $\triangle B_r$ falls below a minimum threshold of ± 0.3 nT per degree latitude. The threshold is chosen well above the noise background, so little noise appears in the figure to obscure the context image. The extraordinary signal fidelity of this map can be appreciated by recognizing that pixels adjacent in longitude are statistically independent, by virtue of the way MGS orbits accumulate. The map spans over two orders of magnitude of signal dynamic range.

The ER instrument of the MAG–ER investigation (Acuña et al., 1992, 1998) provides another means of sensing – remotely – the magnitude of the magnetic field between the spacecraft and atmosphere (Lillis et al., 2004; Mitchell et al., 2007). The technique is similar to that used in lunar orbit to infer surface magnetic field magnitudes (Anderson et al., 1975; Lin et al., 1998; Mitchell et al., 2008) from the properties of the (reflected) electron distribution; however, at Mars, the presence of an absorbing atmosphere must be taken into account (Lillis et al., 2004). Application of this technique at Mars is

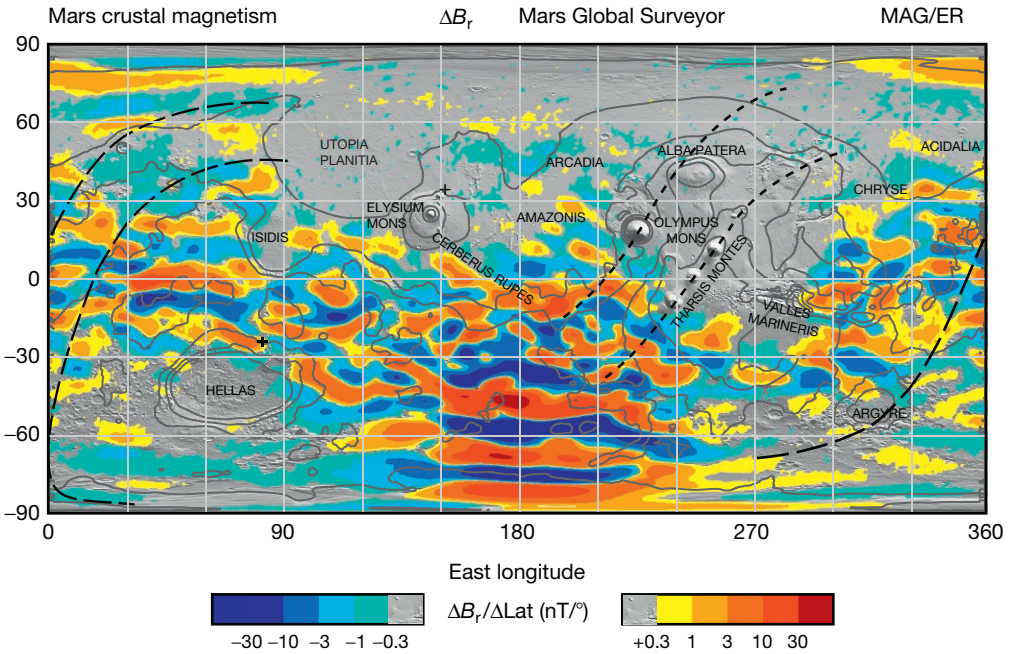

Figure 9 Map of the magnetic field of Mars observed by the Mars Global Surveyor satellite at a nominal 400 km (mapping) altitude. Each pixel is colored according to the median value of the filtered radial magnetic field component observed within the $1^\circ \times 1^\circ$ latitude–longitude range represented by the pixel. Colors are assigned in 12 steps spanning two orders of magnitude variation. Where the field falls below the minimum value, a shaded MOLA topography relief map (Smith et al., 1999) and contours of constant elevation (−4, −2, 0, 2, and 4 km elevation) are shown. Reproduced from Connerney JEP, Acuña MH, Ness NF, Kletetschka G, et al. (2005) Tectonic implications of Mars crustal magnetism. *Proceedings of the National Academy of Sciences* 102(42): 14970–14975.

particularly effective in sensing weaker fields at an altitude of about 170 km above the surface. The ER technique is, however, an indirect method of sensing the magnetic field magnitude at some distance from the spacecraft, and the application of the technique requires attention to detail. The method is based on the magnetic mirror effect and the identification of a population of electrons, sorted by pitch angle, that have reversed their motion along the magnetic field, in response to an increased field magnitude encountered en route to the surface. In the ideal case (adiabatic approximation), an electron follows a helical path along B preserving its energy and magnetic moment, $\mu = mv^2 \sin^2\alpha / 2|B|$, where α is the angle ('pitch angle') between the electron velocity v and the magnetic field. As the electron moves toward an increasing field magnitude, the electron pitch angle rotates toward 90°, at which point the electron reflects (reverses course along B) and is returned to the spacecraft. Electrons with sufficiently small pitch angle (more field-aligned) will not be reflected before reaching the surface (or being absorbed by the atmosphere), and their absence in the electron distribution allows one to identify the maximum magnetic field magnitude encountered between spacecraft and surface. The vector magnetic field measured at the spacecraft is used to infer where (beneath the orbit) the increased field magnitude was encountered and to correct the field magnitude due to crustal sources for externally applied fields. The adiabatic approximation requires that the ratio of the electron gyro radius to the characteristic dimension over which the field changes to be small and that the field does not change appreciably during a gyroperiod. In practice, one must assume that the field does not change direction appreciably between the spacecraft (where it is measured) and the electron's reflection point and that drift motion due to electric fields and magnetic gradients is negligible. Parallel electric fields, which can also reflect electrons, may be recognized by the examination of multiple electron energies (Halekas et al., 2002) and corrected for, where necessary.

A global map of field magnitudes at ~170 km altitude (Mitchell et al., 2007), with a spatial resolution of ~150 km (and using a minimum B threshold of 10 nT at 170 km altitude), compares very well with the map (**Figure 9**) compiled from magnetic field measurements. The broad regions that appear in shaded topography in **Figure 9**, in which the magnetic field falls below threshold, are nearly identical to the weak or zero field regions (to an accuracy of a few nanoteslas) mapped by the ER (Lillis et al., 2008; Mitchell et al., 2007). The ER method works best where field lines are mostly radial at satellite altitude, as over a crustal field well approximated by a radial dipole. The method will return either no result or a less well-constrained result above field lines that are essentially horizontal beneath the spacecraft. The ER method was originally developed to sense magnetic fields above the lunar crust, populated by weak sources of relatively small spatial scale or coherence. In that environment, the field measured at satellite altitude may be straight line continued nearly all the way to the surface, due to the limited reach of the weak crustal sources. At Mars, crustal fields are much stronger and of large spatial scale, limiting the accuracy with which the field may be continued (via the straight-line approximation, i.e., nonself consistently) down toward the reflection point.

10.06.3.3.2 Models

The representations routinely employed throughout the solar system – dipoles and spherical harmonic expansions – lose much of their appeal when applied to the crustal field on Mars. Such global models require an awkward number of model parameters or coefficients to represent the crustal field. For example, Cain's (Cain et al., 2003) spherical harmonic model extends to $N_{max}=90$, requiring $(N_{max}+1)^2-1=8280$ model coefficients to calculate the field at one point above the surface. Likewise, Purucker's many-dipole model (Purucker et al., 2000) uses 11 500 dipoles distributed on a spherical surface ($1R_m$) to represent the field by superposition. There are a variety of spherical harmonic (Arkani-Hamed, 2001a, 2002; Cain et al., 2002) and equivalent source models (Langlais et al., 2004; Purucker et al., 2000) to chose from. These models can be obtained from the authors in electronic form. They offer a means of extrapolating the field from the measurement surface (400 km) and volume spanned by aerobraking passes to nearby points; however, none can be expected to accurately predict the field near the source region.

Mars crustal magnetism is amenable to study using many of the methods and tools developed for interpretation of magnetic surveys on Earth. In *source modeling*, one attempts to fit the observed vector field using one or more magnetized sources, for example, a collection of thin plates and prisms, often guided by constraints suggested by local geology and material properties. General techniques for the *continuation* of a potential field (e.g., Blakely, 1995) may also be applied to extrapolate the field away from a surface upon which the vector field is known. Downward continuation (toward the source) must be done with caution, as it is essentially a differencing operation that amplifies short-wavelength random noise (exponentially in z). Source modeling must also be done with caution, as it is not possible to uniquely determine crustal magnetizations using measurements external to the source.

Connerney et al. (1999) used a source model to fit observations obtained during several aerobraking passes over the intensely magnetized southern highlands (Terra Cimmeria and Terra Sirenum). These quasiparallel features appear lineated in the east–west (cross track) direction; many can be traced over 1000 km in length. The model consisted of multiple uniformly magnetized parallel thin plates, aligned (and extending to infinity) in the east–west direction. The volume magnetization of each strip was determined using a linear inverse methodology to best fit the vector observations along one or more aerobraking passes (**Figure 10**). The observations could be fit well with a model characterized by strips of alternating polarity and volume magnetizations of as much as $\pm 20\ A\ m^{-1}$ (assuming a 30 km thick plate). This figure is likely a lower bound, since only the product of thickness and volume magnetization is constrained by the observations (Connerney et al., 1999). If the magnetization is borne in a thin layer, say 3 km, then volume magnetizations of order $100\ A\ m^{-1}$ would be required. This is a rather astonishing intensity of magnetization required throughout large volumes of crust. At the other extreme, Parker (2003) developed a theory to establish the minimum possible intensity of magnetization consistent with the data modeled by Connerney et al. Interpolating his results to a crustal thickness of 30 km, he found a minimum magnetization intensity of $\sim 10\ A\ m^{-1}$ is required to satisfy MGS observations. Connerney et al. (1999) found the magnetic lineations on Mars sufficiently reminiscent of the pattern of magnetization associated with seafloor spreading on Earth that they proposed a similar mechanism – crustal spreading in the presence of a reversing dynamo – for the evolution of the Mars crust.

Sprenke and Baker (2000) modeled crustal magnetization in the southern highlands using the same aerobraking observations and inverse methods used by Connerney et al. (1999). Their models imposed constraints on the direction of magnetization ('normal' and 'reversed') and allowed for a variation in the intensity of magnetization in the cross track direction. They found similar magnetization intensities and obtained a good fit to the observations with a seafloor spreading model, allowing for variation of magnetization intensity (but not direction) along the stripes. The more uniformly distributed observations obtained at mapping altitude over the same region were downward continued using the Fourier transform method (Jurdy and Stefanick, 2004). Continuation to a 100 km altitude surface allowed a favorable comparison with the aerobraking observations and revealed abrupt lateral changes in field direction and magnitude suggestive of, but not requiring, reversed lineations.

There is great interest in identifying a Mars paleopole, and a number of authors have sought to determine ancient pole position(s) on Mars by fitting various magnetized sources to MGS magnetic field observations (Arkani-Hamed, 2001b; Arkani-Hamed and Boutin, 2004; Boutin and Arkani-Hamed, 2006; Frawley and Taylor, 2004; Hood and Zakharian, 2001; Hood et al., 2010; Langlais and Purucker, 2007; Sprenke and Baker, 2000). A large number of putative paleopoles have been proposed but as yet no consensus has emerged (for a recent compilation, see Milbury et al., 2012). A general consideration of nonuniqueness in the interpretation of potential fields would suggest that without additional constraints, the problem remains intractable (Connerney et al., 2004). In one case where a priori information (a gravity high) may help constrain the location of a magnetic source (one associated with the Apollinaris volcanic edifice), a paleopole location (65° S, 59° E) near the current Mars rotational pole was found by two sets of authors (Hood et al., 2010; Langlais and Purucker, 2007). However, Apollinaris was active a few hundred million years *after* the inferred demise of the dynamo, based on the analysis of the giant impacts (Lillis et al., 2013), which ought to produce a more dependable record of dynamo history. Where the association between volcanism and magnetic field is greatest, volcanism has either completely or partially demagnetized a preexisting magnetic imprint (Connerney et al., 2005); long-lived volcanoes, in bulk and sensed from orbit, are unlikely to be effective recorders of paleofield directions (e.g., Lillis et al., 2013). An alternative approach to locating paleopoles, based on a statistical analysis of many sources (Sprenke, 2005), suggests a preference for paleopoles near 17° N, 230° E, and 17° S, 50° E, near those proposed earlier based on geomorphology and analysis of grazing impacts (Schultz and Lutz, 1988). In another statistical approach, Milbury and Schubert (2010) searched among a distribution of paleopoles, assigning a magnetization intensity and direction to portions of the crust, in such a way as to best match the observed magnetic field, taken, for convenience, from several spherical harmonic model representations. They

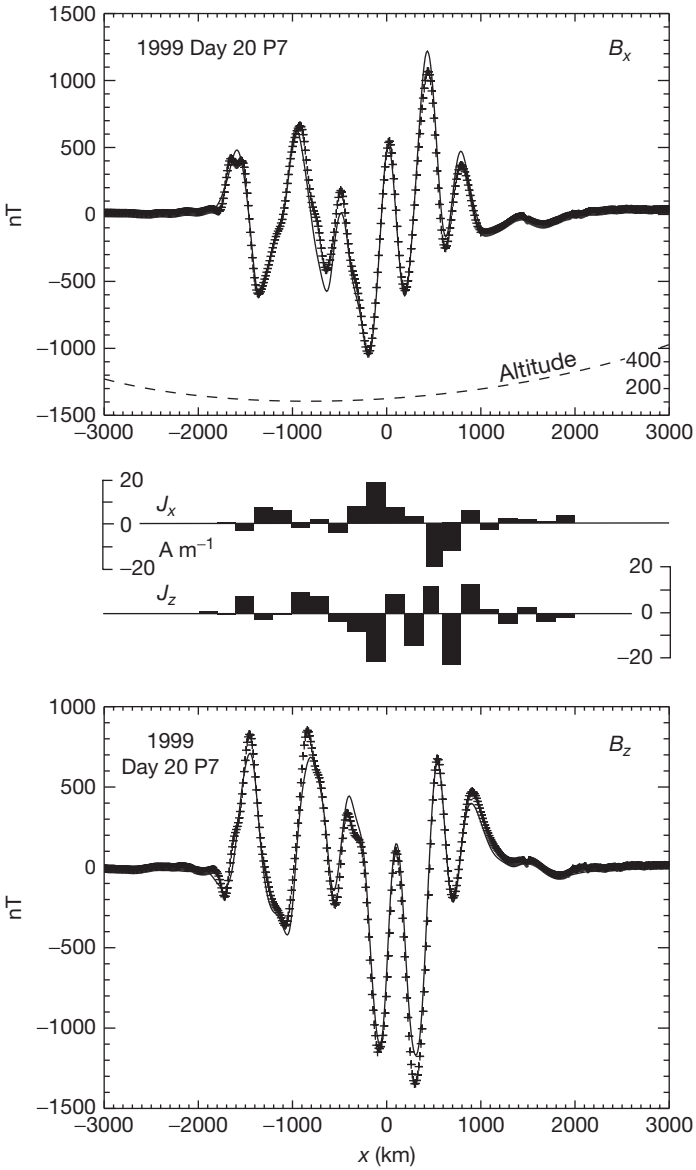

Figure 10 Vector magnetic field measured by MGS during aerobraking on calendar day 20, 1999. Periapsis occurred at 68.0° S, 181.2° W and 106 km altitude. The x (north) and z (down) components of the vector field sampled every 3 s (crosses) are compared with a model fit (solid line). Altitude variation in kilometers indicated with a dashed line. Observations plotted as a function of distance x north and south of an origin at 53° S and at the longitude of periapsis. Model consists of 20 uniformly magnetized slabs aligned with the y-axis (east–west) and infinite in extent along y. The x and z components of the model crustal magnetization per unit volume (A m^{-1}) are indicated in the bar graphs between the two panels. Reproduced from Connerney JEP, Acuña MH, Wasilewski PJ, Ness NF, et al. (1999) Magnetic lineations in the ancient crust of Mars. *Science* 284: 794–798.

found a weak but significant correlation for spherical harmonic degrees 2 and 3 and a set of paleopoles and none for higher degrees. This may indicate that only a global-scale correspondence exists, but it may also reflect a sampling bias, in that large portions of the crust (northern lowlands, Tharsis complex, and major impact basins) were removed from the model. The paleopoles are found at low latitudes to midlatitudes and are suggestive of polar wander and polarity reversal (Milbury and Schubert, 2010). Coexistence of near-equatorial and near-polar paleopoles can be reconciled with the expectation of a moderate angular separation of dipole (magnetic) and rotational axes if one invokes significant polar wander during the active dynamo era (e.g., Boutin and Arkani-Hamed, 2006; Milbury et al., 2012; Sprenke, 2005).

10.06.3.3.3 Discussion

Mars has no global field and therefore no dynamo at present, but must have had one in the past when the crust acquired intense remanent magnetization. It is likely that a molten iron core formed early, after or during hot accretion 4.5–4.6 Ga, and for at least a few hundred million years, a substantial global field was generated by dynamo action in the core. The chronology proposed by Acuña et al. (1999) attributes the global distribution of magnetization to an early demise of

the dynamo, prior to the last great impacts (~4 Ga) that left large unmagnetized basins in the crust. This view has been supported by more complete analyses of the large impact basins (Lillis et al., 2008, 2013), leading to more precise estimates of the dynamo's demise (activity extinguished before formation of Hellas and Utopia basins 4.0–4.1 Ga). Schubert et al. (2000) argued in favor of a late onset of the dynamo and proposed that the southern highlands crust acquired magnetization from local heating and cooling events that postdate the era of large impacts and basin formation. Early onset and cessation of the dynamo are difficult to reconcile with the notion of a dynamo driven by solidification of an inner core (Schubert et al., 1992), the preferred energy source for the Earth's dynamo. Alternatively, an early dynamo can be driven by thermal convection, with or without plate tectonics, for the first 0.5–1 Gy (Breuer and Spohn, 2003; Connerney et al., 2004; Schubert and Spohn, 1990; Stevenson et al., 1983), persisting as long as the core heat flow remains above a critical threshold for thermal convection (Nimmo and Stevenson, 2000).

After more than 2 full years of mapping operations, MGS produced an unprecedented global map of magnetic fields produced by remanent magnetism in the crust (Connerney et al., 2005). This map (**Figure 9**) reveals contrasts in magnetization that appear in association with known faults, variations in magnetization that are clearly associated with volcanic provinces, and magnetic field patterns that appear shifted along small circles in the manner of transform faults at spreading centers (Connerney et al., 2005). Connerney et al. proposed that the entire crust acquired a magnetic imprint via spreading in the presence of a reversing dynamo and that erasure of this imprint occurred where the crust was buried (thermal demagnetization) by flood basalts to depths of a few kilometers. In the remaining magnetic imprint, one can identify the telltale signature of transform faults, in Meridiani Planum, and the signature of craters that formed both before and after the demise of the dynamo. Of course, transform faults are unique to plate tectonics, so if these features are indeed transform faults, then the Mars crust formed via seafloor spreading as on Earth (Connerney et al., 1999; Sleep, 1990). The interpretation of this map is not without controversy, and many regard the seafloor spreading analogy championed by Connerney and colleagues as speculative, in large part due to the paucity of correlative observations. The alignment of the great volcanic edifices on Mars is consistent with plate motion over a mantle plume (Connerney et al., 2005) or, conversely, volcanic chains formed above subducting slabs (Sleep, 1990, 1994; Yin, 2012, personal communication). The topographical relief along much of the dichotomy boundary has been interpreted as a series of ridge/transform fault segments (Sleep, 1994). A recent structural analysis of the Valles Marineris fault zone (Yin, 2012) likens this trough system to the left-slip, transtensional Dead Sea fault zone on Earth joining the Red Sea spreading center to the Zagros suture zone in the north: an undisputed plate boundary. It is difficult to understand how such a structure evolved on Mars in the absence of plate tectonics.

Fairen et al. (2002) proposed that the magnetic lineations might instead be the signature of accretionary terrains formed during an early era of plate tectonics, while others have proposed the formation of a series of quasiparallel dike intrusions as alternatives to the crustal spreading hypothesis (Hood et al., 2007; Nimmo, 2000; Ravat, 2011). Using an automated cluster analysis of lineated features in Connerney et al.'s (2005) map, Kobayashi and Sprenke (2010) identified two groups, or clusters, of features that they attributed to thermoremanent magnetization of chains of intrusions formed by lithospheric drift over mantle hot spots. However, none of these proposed mechanisms manufacture magnetic material with the uniformity, efficiency, and spatial scale of crustal spreading in the presence of a global magnetic field. To account for the enormous magnitude of the field above the Mars crust, one requires a great deal of material coherently magnetized with a rather startling intensity of magnetization. It is difficult to imagine any process that can compete with seafloor spreading in this regard.

Magnetic mapping is an even more powerful tool on Mars than on Earth, where it has been indispensible in understanding the evolution of the Earth, especially in the development of the unifying theory of plate tectonics. On Earth, magnetic surveys are complicated by the presence of the main field, which makes measurement of crustal anomalies challenging: the Earth's magnetic anomalies are very weak, compared to the main field, resulting in limited signal to noise in the measurement. Magnetic anomalies are also more difficult to interpret on Earth because they may result from either induced or remanent magnetization, or both. Mars, lacking a main field, is free of such complications; the global map of its crustal field is quite remarkable, affording an opportunity to apply the methods of exploration geophysics on a global scale. It is clear that the crust of Mars retains a magnetic imprint of its formation and subsequent evolution. That history may be read with increasing resolution as magnetic surveys are conducted at lower altitudes. One may anticipate great insights from such surveys as well as from Mars paleomagnetism when that field develops.

10.06.4 Gas Giants

10.06.4.1 Jupiter

Jupiter, the largest ($R_j = 71\,372$ km) and most massive ($M_j = 318 M_e$) planet in the solar system, resides at a mean orbital distance of 5.2 AU from the Sun. Jupiter, capturing much of the gas component of the solar nebula, is largely a solar mix of H and He, possibly with a rock and ice core of some tens of Earth masses. The Jovian system has been visited often by spacecraft, both as a destination and as a waypoint for vessels destined to travel onward. A passing spacecraft can use Jupiter's considerable mass and orbital velocity to advantage, acquiring a boost to greater radial distances (e.g., Cassini and New Horizons to Pluto) or to achieve higher solar latitudes (e.g., Ulysses), than would otherwise be possible. Thus, Jupiter's orbit serves as a crossroads for travelers to other worlds as well.

Jupiter was known to have a magnetic field long before the first *in situ* observations were obtained. Burke and Franklin (1955) had detected nonthermal decameter wavelength emissions (22 MHz) from Jupiter, leading to speculation that Jupiter possessed a magnetic field of internal origin. Observations at decimetric (~1 GHz) wavelengths subsequently revealed synchrotron radiation, emitted by high-energy electrons trapped in a Jovian Van Allen belt. This emission, as observed, is modulated by the rotation period of the planet (9.925 h). Since synchrotron radiation is narrowly beamed in a direction

perpendicular to the magnetic field guiding the electron motion, the modulation can be used to infer the geometric properties of the field. Thus, the tilt (9.5°) and phase (200° λ_{III}) of the Jovian dipole were deduced (Morris and Berge, 1962), and estimates of the dipole offset (from the origin) were made (Warwick, 1963), well before the first spacecraft arrived at Jupiter. The magnitude of the field, however, remained in doubt.

Continued observations of Jovian radio emission at decameter wavelength revealed yet another periodicity in the occurrence of radio storms, one that matched the orbital period (42.46 h) of the innermost Galilean satellite, Io (Bigg, 1964). The intensity and occurrence rate of radio storms vary dramatically with Io's orbital phase, as well as Jovian central meridian longitude. Activity peaks when Io's orbital phase is near 90° and 240° (measured in the direction of Io's orbital motion from geocentric superior conjunction). Io's influence on Jovian radio emissions was attributed to an electrodynamic interaction (Goldreich and Lynden-Beil, 1969) that drives currents along magnetic field lines to and from Jupiter's magnetosphere.

10.06.4.1.1 Observations

Pioneer 10, the first spacecraft to enter the Jovian magnetosphere, passed within 2.8R_j of the planet at closest approach in December 1973. Pioneer 10's flyby trajectory carried it through the Jovian system at relatively low magnetic latitudes (Figure 11). This region, near the equator, is home to a large-scale system of azimuthal currents (ring currents) extending from about 5R_j to the outer reaches of the magnetosphere (~100R_j). This current system imparts a disklike geometry to the magnetic field, with field lines at great distances stretched nearly parallel to the equator (leading to the descriptive 'Jovian magnetodisk'). Precisely 1 year later, Pioneer 11 approached to within 1.6R_j on a retrograde λ_{III} trajectory. The Pioneer 11 trajectory provided measurements over a wide range of magnetic latitudes (Figure 11) and longitudes.

The Pioneer 10 and 11 spacecrafts were instrumented to measure magnetic fields with a vector helium magnetometer (VHM) provided by the Jet Propulsion Laboratory (Smith et al., 1975b). This instrument could measure a maximum of ±1.4 G in the highest of its eight dynamic ranges. Pioneer 11 also carried a small high-field triaxial FGM provided by the Goddard Space Flight Center (Acuña and Ness et al., 1976). The FGM was added as a precaution, to extend measurement capability to a field of 10 G along each axis (the Earth's field magnitude ~0.6 G at the pole). The magnitude of Jupiter's field was unknown at the time of launch, and the concern was that without a high-field instrument, Pioneer 11 might not have the dynamic range needed to make observations throughout the encounter. Fortunately, the maximum field experienced by Pioneer 11 was ~1.12 G, observed just as the spacecraft went into occultation on its way to closest approach at 1.6R_j. There are small but significant differences between the two data sets that have not been fully resolved, so most analyses have tended to use data from one or the other but not both.

The two Voyager encounters followed in March and July of 1979. Like Pioneer 10, the Voyagers remained near the Jovigraphic equator, confined to relatively low magnetic latitudes. Voyager 1 was targeted for a close flyby of Io and the Io flux

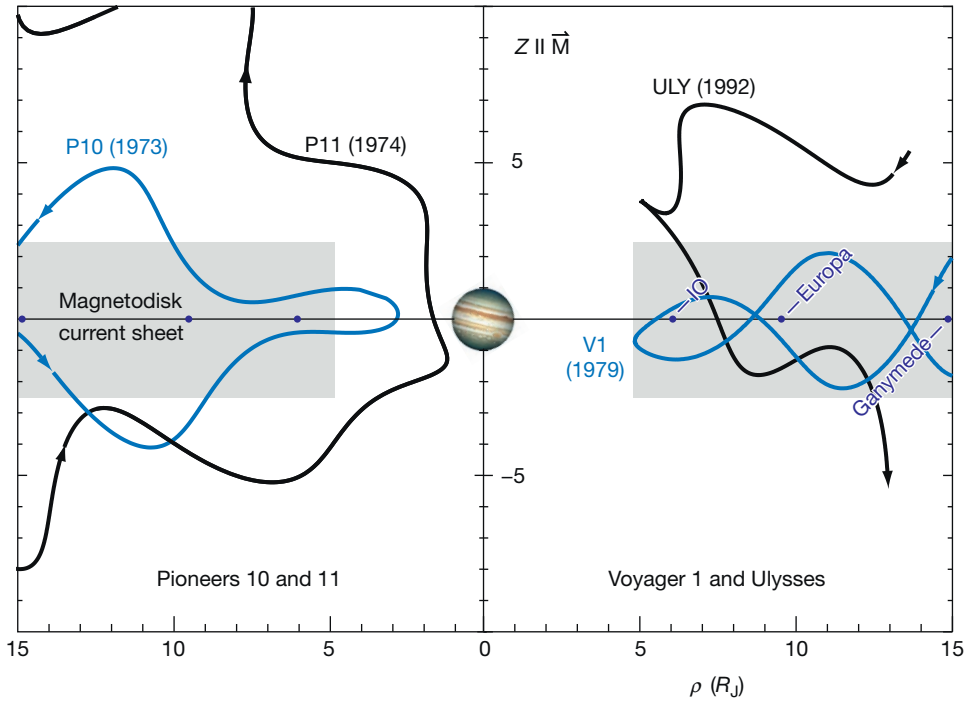

Figure 11 Spacecraft flybys (Pioneer 10 and 11, Voyager 1, and Ulysses) of Jupiter in a magnetic equatorial (cylindrical) coordinate system. The z-axis is aligned with Jupiter's magnetic dipole axis. The spacecraft distance from the magnetic equator (z) as a function of distance from the z-axis (ρ) is given in units of Jupiter radius. The Galilean satellites Io, Europa, and Ganymede trace out arcs (not shown) in this coordinate system crossing the equator at the radial distances indicated. The shaded region approximates the washer-shaped system of azimuthal ring currents that gives rise to the magnetodisk configuration of the Jovian magnetosphere.

tube (IFT); its closest approach to Jupiter was $4.9R_j$, just inside the orbit of Io ($5.95R_j$). The maximum field measured by Voyager 1 was just ~3330 nT (Ness et al., 1981). The Voyager 2 flyby was relatively distant, with a closest approach distance of $10R_j$ (Ness et al., 1982). In this region of the magnetosphere, the measured magnetic field has a significant contribution due to the magnetodisk currents. These will tend to reduce the θ component of the planetary field near the equator and introduce a component of the field in the radial direction that changes sign in crossing the magnetic equator. Local currents cannot be modeled with potential fields and, if present, may lead to large errors in estimates of the planetary field if not accounted for (Connerney, 1981).

Jupiter was not visited again until the Ulysses flyby on 8 February 1992, more than two decades after the Voyager flybys (Balogh et al., 1992). Ulysses was designed to study the heliosphere at high solar latitudes; the Jupiter flyby was used to kick the spacecraft into a high-inclination orbit about the Sun. The spacecraft approached Jupiter at relatively high northern latitude, measuring a maximum field of 2372 nT just after closest approach at $6.3R_j$. This encounter was much like that of Voyager 1, in that for much of the time near closest approach, the spacecraft was immersed in the local currents of the Jovian magnetodisk.

The recently completed Galileo mission to the Jovian system was designed to deliver an atmospheric probe, explore the distant magnetosphere, and provide opportunities for many satellite encounters (Johnson et al., 1992). Galileo's mission plan was not well suited to provide appreciable additional information on the planetary field. Likewise, the Cassini spacecraft encounter was a distant flyby, engineered to speed the spacecraft onward to its destination (Saturn) in the outer solar system. The spacecraft that passed relatively close to Jupiter did so once, providing *in situ* observations along but one path; the spacecraft (Galileo) that enjoyed multiple orbits remained at a distance and near the equatorial plane. In order to characterize Jupiter's magnetic field, and the dynamo that generates it, observations must be obtained at close-in radial distances (where higher-degree and higher-order harmonics of the field are relatively large) and well distributed globally about the planet. The Juno spacecraft launched in August 2011 and now en route to Jupiter for a July 2016 arrival (Bolton et al., 2010) will do just that. Juno's mission plan wraps the planet in a net of observations (**Figure 12**) provided by 32 near-polar orbits with periapsis just above the cloud tops, uniformly distributed in longitude (separation of 12°). The Juno magnetic field investigation is designed to map Jupiter's magnetic field with very high accuracy, sufficient to characterize the field to degree and order 12–15, depending on the dynamo core radius (estimated $0.75–0.85R_j$) and other assumptions (Connerney et al., 2014).

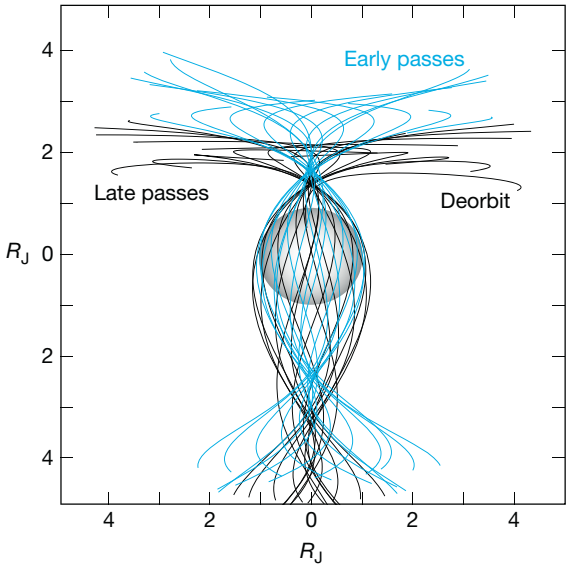

Figure 12 Orthographic projection of the near Jupiter ($r < 5R_j$) portion of Juno's 11-day science orbits. Orbits 2–16 (blue) are acquired in the first 6 months of mapping and are equally spaced in longitude (at closest approach) by 24°. Orbits 17–31 (black) are acquired after a trajectory correction that places these passes between those already acquired, resulting in complete global coverage with longitude spacing of ~12°. Juno's insertion into orbit about Jupiter (JOI) occurs in July 2016.

10.06.4.1.2 Models

The large number of Jovian magnetic field models available is a result of several factors, interest in the Jovian system undoubtedly foremost among them. There is a wealth of observations of Jovian phenomena, many of which (e.g., radio emission and auroras) depend critically on details of the magnetic field near the planet where few direct observations exist. The need is great. In addition, techniques for modeling the field have evolved, and improved, in part in response to the challenges of separating the planetary field from that produced by external currents. Techniques have also evolved to take advantage of new observations (e.g., emission from the foot of the IFT) that serve as valuable constraints on the field near the surface. Here, we describe a subset of the available models, intended to illustrate the development of new approaches.

The first models of Jupiter's planetary field were the OTD approximations (D2 and D4) obtained from the Pioneer 10 and 11 VHM observations (Smith et al., 1976). Analyses of the Pioneer 11 FGM observations suggested that a more capable parameterization was needed, leading to development of the O_4 model (Acuña and Ness, 1976), the first of many spherical harmonic models of Jupiter's internal field. This model and the spherical harmonic analysis (SHA) model of Smith et al. (1976) allowed spherical harmonics of degree and order 3 (octupole) for the internal field and approximated external fields with external harmonics of degree 1 or 2. **Table 3** gathers together the spherical harmonic coefficients of several models, fit to various subsets of data and using a variety of methods. Estimated errors are given for some of these models, but not reproduced here, for brevity. The original publication should be consulted.

The Pioneer 11 VHM and FGM observations have proved most useful for studies of the planetary field, in large part due to the relatively good spatial distribution of observations afforded by that spacecraft's trajectory. The problem of inverting flyby observations to obtain estimates of the spherical harmonic coefficients has been posed as an eigenvalue problem and solved using the SVD method (Connerney, 1981). This technique allows partial solutions to underconstrained linear inverse problems and can be used to show how even

Schmidt normalized spherical harmonic coefficient in nT, referenced to Jupiter system III (1965) coordinates, and $1R_j = 71\,398$ km for Ulysses; $1R_j = 71\,323$ km for Voyager 1.
Voyager 1 17ev model from Connerney et al., 1982a,b. Models VIP4 and VIT4 used the magnetodisc model fitted to Voyager 1 observations (V1-17ev) as fixed parameters.
The notation 'UR' refers to unresolved parameters. Pioneer 11 O_4 model coefficients as tabulated for system III (1965) by Acuña et al., 1983a,b (originally (1957 system III) from Acuña and Ness, 1976).
Pioneer 11 SHA model originally (1957 System III) from Smith et al. (1976).

small measurement errors – such as noise or unmodeled external fields – can lead to large errors among the internal field coefficients. Pioneer 11 also remained largely outside of the region of current flow (equatorial magnetodisk) near closest approach, so external fields are less of a problem.

The Voyager 1 observations yielded a considerably reduced dipole moment, upon preliminary analysis, which was attributed to the presence of magnetodisk currents that were not adequately modeled (Ness et al., 1979a). Subsequent analyses of the Voyager 1 observations used an explicit model of the magnetodisk (Connerney et al., 1981) in combination with a spherical harmonic model for the planetary field. An inversion scheme that allowed for the variation of the parameters of the magnetodisk along with those of the internal field resulted in a partial octupole model (V1 17ev) of the planetary magnetic field (Connerney et al., 1982a). The Voyager 1 model of the field (epoch 1979) could be compared with the Pioneer 11 model (GSFC O_4) of the field (epoch 1973) to limit Jovian magnetic secular variation (g_1^0) to no more than 0.2% per year (Connerney and Acuña, 1982). By comparison, the present-day decrease in the terrestrial g_1^0 term is about 0.075% per year.

Preliminary analysis of the Ulysses encounter observations (Balogh et al., 1992) suggested good agreement with the magnetic field calculated using the O_6 planetary field augmented with a magnetodisk current sheet model (Connerney et al., 1981) if one allowed for variations of the external field during the encounter. The Ulysses close approach observations were obtained in the immediate vicinity of the inner edge of the current sheet, so some attention to external fields is required. Dougherty et al. (1996) found the data consistent with Connerney's O_6 model, allowing for a reduction of the g_1^0 coefficient (main dipole term), from 4.242 to 4.059 G. Connerney et al. (1996) derived an octupole model of the field (Ulysses 17ev), also with a reduced dipole g_1^0 coefficient (4.109 G), and demonstrated that the internal zonal harmonic coefficients covary with the parameters of the current disk, complicating attempts

to separate internal and external fields. The magnetodisk current system was considerably weaker during the Ulysses epoch, relative to that observed during the Pioneer and Voyager epochs. Connerney et al. (1996) quoted a figure of 20% less total integrated magnetodisk current at the time of Ulysses encounter, Dougherty et al. (1996) quoting a 28% reduction. Differences among the Ulysses era (Ulysses 17ev) model and those of Voyager (Voyager 1 17ev) and Pioneer (O_4) appear within, or comparable to, the estimated parameter errors (Connerney et al., 1996); so there is little evidence of secular variation of the main field from these data (Connerney and Acuña, 1982; Dougherty et al., 1996) or from the more distant observations acquired throughout Galileo's tour (Russell and Dougherty, 2010; Yu et al., 2009).

The O_6 model of Jupiter's magnetic field used observations from both Pioneer 11 (1973) and Voyager 1 (1979), assuming that the magnetic field has not changed appreciably between encounters and adds a constraint on Jupiter's harmonic spectrum (Connerney, 1992). This model was designed to benefit from the better spatial distribution of observations afforded by combining trajectories. It was also designed to allow for the possibility that unmodeled fields of higher degree and order than octupole might be present in the observations (particularly those of Pioneer 11, passing to within $1.6R_j$). This model represents a partial solution to an underdetermined inverse problem (spherical harmonic expansion to degree and order 6) combined with an explicit model of the magnetodisk. Another distinguishing feature of this model was the application of a weight $(r_c/a)^{n+2}$ to parameters of degree n, where r_c, the core radius, was taken to be $0.7R_j$. This weighting encourages a model solution with terms of degree n contributing equally to the mean-squared field amplitude on the (presumed) core boundary, as is observed for Earth, through degree 12 or so (Langel, 1987). The Schmidt coefficients of this model ('O_6' for octupole part of a degree 6 expansion) are listed in **Table 3**. The O_6 model is characterized by smaller quadrupole and octupole moments, relative to the comparable O_4 model of Acuña and Ness (1976) and in that regard is more Earth-like in harmonic content (**Figure 13**).

The discovery of infrared emission at the foot of the IFT in Jupiter's ionosphere (Connerney et al., 1993) provided an entirely new and extremely valuable constraint on magnetic field models. This emission occurs in Jupiter's polar ionosphere where field lines threading the satellite Io (or its conducting ionosphere) at an orbital distance of $5.95R_j$ intersect the Jovian ionosphere. The feature is observed to move across the disk of Jupiter in concert with Io's orbital motion, tracing a path around each magnetic pole (**Figure 14**). This path serves as a fiducial marker, providing an unambiguous reference on

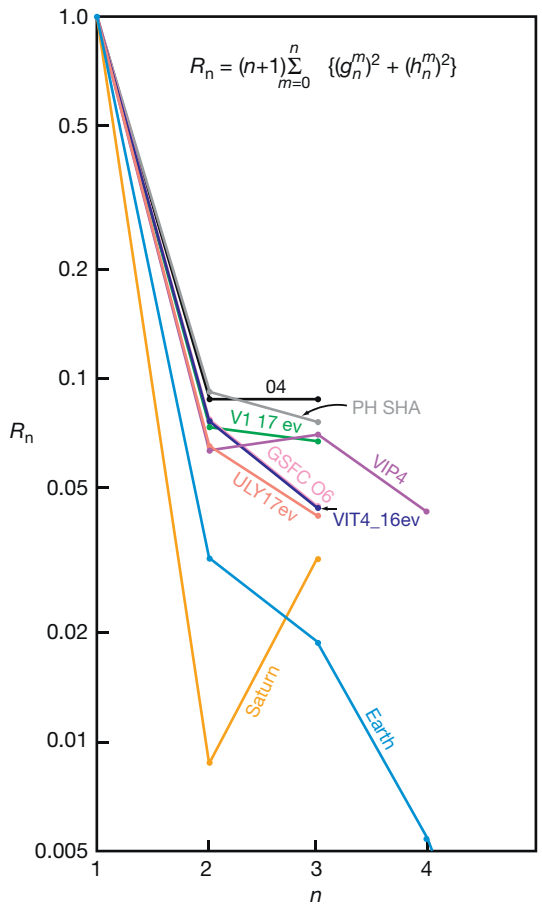

Figure 13 Relative harmonic content (Lowes' spectrum) of spherical harmonic models of the Jovian field, compared with that of Earth and Saturn.

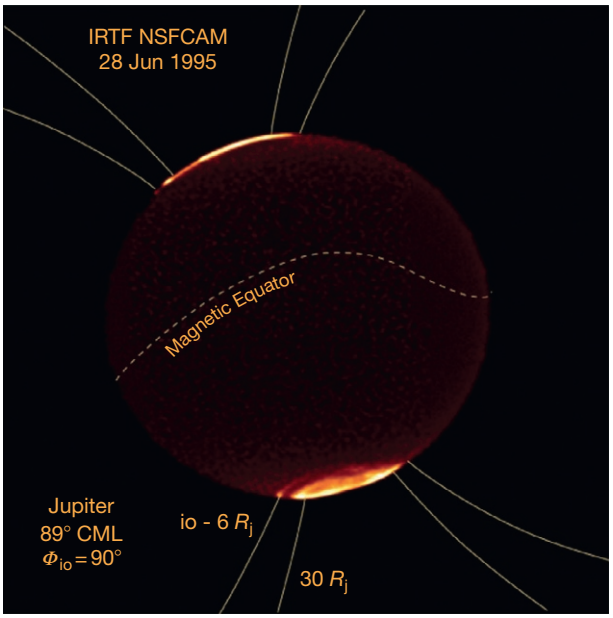

Figure 14 Image of Jupiter at 3.4 μm obtained at NASA's IRTF at Mauna Kea, Hawaii, using the NSFCAM facility imager. At this wavelength, bright H_3^+ auroral emissions originating above the homopause appear against a planetary disk darkened by methane absorption. Magnetic field lines are drawn in meridian plane projection to illustrate where field lines crossing the equator at $30R_j$ and $6R_j$ (Io's orbit) intersect Jupiter's surface. A bright emission feature at the foot of the Io flux tube (IFT) can be identified near the dawn limb, as well as faint emission extending along the Io L-shell downstream of the instantaneous IFT. Reproduced from Connerney JEP and Satoh T (2000) The H_3^+ ion: A remote diagnostic of the Jovian magnetosphere. *Philosophical Transactions of the Royal Society of London* 358: 2471–2483.

Jupiter's surface through which magnetic field lines with an equatorial crossing distance of $5.95R_j$ must pass. Thus, observations of the location (latitude, longitude) of the footprint offer a unique constraint on magnetic field models, precisely where it is most needed, on the surface of the planet, and otherwise unavailable. This emission is observable from Earth with ground telescopes (e.g., Infrared Telescope Facility on Mauna Kea) in the infrared region of the spectrum (Connerney and Satoh, 2000; Connerney et al., 1993) and with the Hubble Space Telescope in the ultraviolet region (Bonfond et al., 2009; Clarke et al., 1995, 1996, 2005; Prange et al., 1996). Emission has now been detected at the foot of the Europa and Ganymede flux tubes as well (Clarke et al., 2002; Grodent et al., 2006, 2009). The Europa and Ganymede observations are less useful constraints on the internal field because these field lines pass through the equator at greater radial distance (9.4 and $15R_j$, respectively) where relatively large and time-variable external fields are encountered. However, the Ganymede footprint supplies a useful fiducial marker for locating the source of the main aurora (Clarke et al., 2002), since emissions poleward of the Ganymede footprint must map to regions beyond its orbit ($15R_j$).

Over 100 determinations of the location of the IFT footprint were combined with *in situ* magnetic field observations (Pioneer 11 VHM and Voyager 1 FGM) to obtain a partial solution to a fourth-degree and fourth-order expansion of the internal field (Connerney et al., 1998). This model is referred to as the 'VIP4' model (**Table 3**), reflecting the use of Voyager 1, IFT, and Pioneer observations and an internal spherical harmonic expansion to degree and order 4. This model was designed to fit the position of the IFT footprint very well (within $\sim 1^\circ$ latitude), so it has proved particularly useful in analyses of satellite interactions and auroras. However, no one model fits the IFT footprints and *all* of the *in situ* magnetic field observations to within their expected errors (Connerney et al., 1998), although the IFT observations can be so fit with any *one* set of flyby observations.

Surprisingly, the IFT footprint observations are nearly sufficient *by themselves* to yield a useful field model. All that is needed is a means of constraining the magnitude of the field. The final model in **Table 3** lists a model derived using over 500 IFT footprint locations (Connerney et al., in preparation). This model constrains the field magnitude using a minimum of *in situ* magnetic field data: the theta component, only, of the Voyager 1 closest approach data obtained within $7R_j$. The Voyager 1 data were chosen as the most accurate ($\sim$0.1%) available and the theta component, ranging from 1036 nT to a maximum of 3280 nT, as the least influenced by external fields (larger in magnitude than the radial component of the external field but easily modeled). This model ('VIT4,' reflecting use of IFT observations, Voyager theta component, degree and order 4) is essentially a product of remote observation, using just enough *in situ* data to constrain the magnitude of the field. In principal, any constraint on the field magnitude – such as the field magnitude on the surface, deduced from the maximum frequency of radio emission at the electron cyclotron frequency – would serve as well if properly understood.

Spherical harmonic models confined to relatively low degree and order (e.g., 4) fit the IFT footprint observations well, but there remains a systematic and nonnegligible residual, particularly in the area of the 'kink' that appears in UV observations of satellite footprints and auroras near 110° Jovian system III longitude. Grodent et al. (2008) had suggested that a more localized source, or magnetic anomaly, might account for the 'kink.' This additional source could not be uniquely determined, but these authors demonstrated that the observations of satellite and auroral footprints in the northern hemisphere can be reproduced using a model of this type. The putative magnetic anomaly would necessarily have to be located near the surface in order to modify the satellite and auroral footprints without dramatically altering the field elsewhere. In perhaps the most ambitious such modeling attempt to date, Hess and coworkers utilized an extensive database of IFT footprints compiled by Bonfond et al. (2009) to obtain a fifth-degree and fifth-order spherical harmonic model ('VIPAL') of the Jovian magnetic field (Hess et al., 2011). This model obtains a better fit to the satellite footprints, at the expense of a poorer fit to the *in situ* magnetic field observations inward of about $4R_j$. However, VIPAL was also constrained to minimize the longitudinal separation between the observed and the modeled IFT footprints, and it was adjusted to produce a prescribed surface magnetic field strength along the IFT 'footpath.' This was done to better match the local electron gyrofrequency to observations of Jovian radio emissions, under certain assumptions regarding the source location, beaming, and generation of radio emissions. Thus, models of this type (e.g., VIPAL) require a certain degree of confidence in our understanding of the propagation of Alfven waves from Io to Jupiter (longitude constraint) and a degree of confidence in our understanding of the generation and propagation of Jovian radio emissions (surface magnitude constraint) as the price to be paid for encompassing more observables. In contrast, models based entirely on *in situ* magnetic field observations rest on our unshakable faith in the extrapolation of a potential field through a region of space devoid of local currents. In a few short years, the Juno spacecraft will enter Jupiter orbit (July 2016) to map Jupiter's magnetic field both closer to the planet and with much greater accuracy than ever before. Shortly after Juno's prime mission begins, it should be possible to discriminate among the approaches outlined earlier.

10.06.4.1.3 Discussion

The magnitude of the surface field for the O_6 model ranges from just over 3 G at low latitudes to just over 14 G at high (northern) latitudes. This is similar to the range of field magnitudes predicted by the O_4 model of Acuña and Ness (1976). The variation of magnetic field magnitude on the surface of Jupiter is illustrated in **Figure 15**, which depicts contours of constant field magnitude on the dynamically flattened surface of Jupiter, computed using the VIT4 model. This model has a less prominent north–south asymmetry in the magnetic field magnitudes, compared to earlier models; the maximum field in the northern hemisphere (13.9 G) is comparable to that of earlier models (see Acuña et al., 1983a,b), but the maximum field in the southern hemisphere (13.2 G) is considerably larger. The estimated uncertainty in the surface field magnitude is about ± 1 G (Connerney, 1981, 1992) but could be appreciably greater if higher-degree and higher-order harmonics are larger than expected or, equivalently, if a near-surface

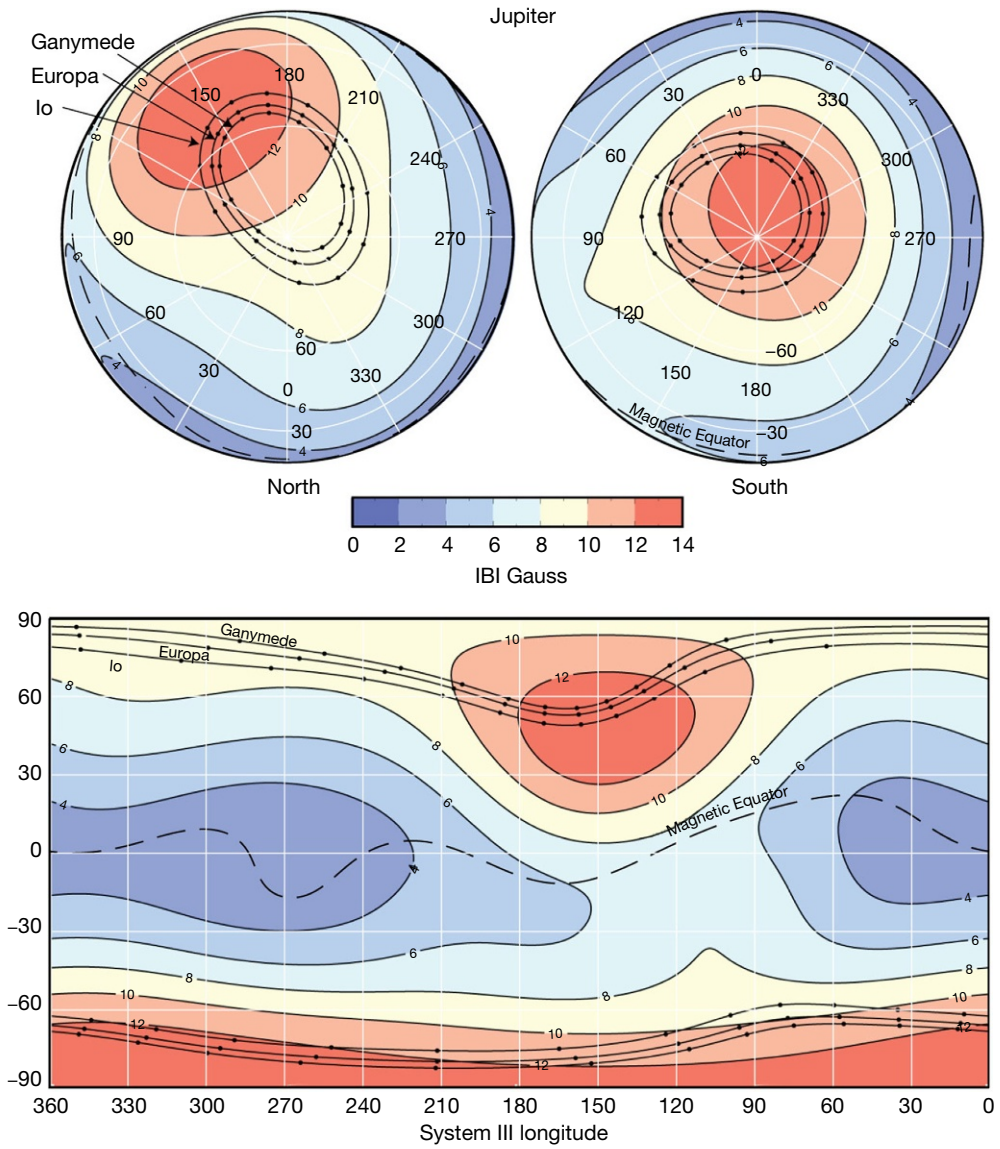

Figure 15 Contours of constant magnetic field magnitude (Gauss) on the dynamically flattened (1/15.4) surface of Jupiter, computed using the VIT4 model field (see text). The top panel shows the field magnitude in orthographic projections viewed from the north (left) and south (right); below the color bar is a rectangular latitude–longitude (system III west longitude) projection. A trace (dashed) indicates the position of the magnetic equator. Solid lines join points on the surface that trace along field lines to the orbits of the Galilean satellites Io, Europa, and Ganymede, with filled circles for increments of 30° in the satellite's system III longitude.

'magnetic anomaly' is invoked (e.g., Grodent et al., 2008). Modeled surface magnetic field magnitudes for the VIP4 and VIPAL models are not dramatically different (Hess et al., 2011); however, Grodent et al.'s magnetic anomaly model results in much larger surface field magnitudes in the northern mid-latitudes near 150°–180° system III longitudes. Figure 15 also illustrates the foot of the IFT ('Io foot'), which is the path traced out on the planet's surface by the field lines that pass through the satellite Io as the planet rotates. The foot of the IFT passes through the region of highest field strength in the northern hemisphere at a longitude of about 150° λ_{III}. The maximum surface magnetic field magnitude present along the Io foot is generally consistent with the maximum frequency extent (39.5 MHz) of Jovian decameter radio emission, assuming that the emission occurs at the local electron gyrofrequency and at the foot of the IFT (f_c(MHz) = 2.8B (G)). However, significant challenges arise in modeling Jovian radio emissions using such models, and this has motivated a number of authors to explore alternatives.

10.06.4.2 Saturn

Saturn, the second largest (R_s = 60 330 km) and most massive (M_j = 95M_e) planet in the solar system, resides at a mean orbital distance of 9.5 AU, nearly twice as far from the Sun as Jupiter. Like Jupiter, Saturn exhibits the characteristics of a condensed object of solar composition. Saturn was assumed to be much like its larger companion before Pioneer 11 arrived.

However, unlike Jupiter, Saturn as a radio source was relatively quiet. Saturn is too weak a radio source and too distant to be easily detected from Earth. In addition, Saturn emits at lower frequencies (a few kilohertz to 1 MHz) than Jupiter, well below the critical frequency required to penetrate the Earth's ionosphere. Thus, Saturn's radio emissions cannot be routinely monitored using terrestrial radio receivers.

10.06.4.2.1 Observations

The discovery of Saturn's magnetic field was thus left to Pioneer 11, arriving in September 1979, following its Jupiter swingby. The particle and field investigations on board Pioneer 11 (see previous section) obtained observations along a spacecraft trajectory that remained within $\sim 6^\circ$ of the equator (**Figure 16**). The most remarkable feature of Saturn's magnetic field proved to be the close alignment of the magnetic dipole and rotation axes (Acuña and Ness, 1980; Acuña et al., 1980; Smith et al., 1980a), also noted by the charged particle investigations (Simpson et al., 1980; Van Allen et al., 1980). Pioneer 11 approached to within $1.35R_s$, measuring a maximum field of ~8200 nT at -6° latitude (Smith et al., 1980a,b).

The Voyager 1 encounter in November 1980 and the Voyager 2 encounter in August 1981 provided the first observations of Saturn's magnetic field at high northern and southern latitudes (Ness et al., 1981, 1982). Voyager 1 sampled relatively high latitudes (-40°) at close radial distance ($3.07R_s$) but remained in the southern hemisphere while inside of $6R_s$ radial distance. Voyager 1 measured a maximum field of 1093 nT at -40° latitude and 184° SLS longitude, just prior to closest approach (Ness et al., 1981). Voyager 2's closest approach of $2.69R_s$ occurred at 323° longitude, diametrically opposite to those of Pioneer 11 and Voyager 1. Voyager 2 sampled relatively high latitudes in both hemispheres and measured a maximum field of 1187 nT just prior to closest approach (Ness et al., 1982).

More than two decades passed before the arrival of Cassini at Saturn. The Cassini spacecraft has been in orbit about Saturn since its orbit insertion (SOI) on 30 June 2004 and has remained relatively distant subsequent to the orbit insertion maneuver (Dougherty et al., 2004), targeting multiple satellite flybys from the vantage point of a near-equatorial orbit. During SOI, the spacecraft periapsis was just $1.33R_s$; this is the closest Cassini would come to Saturn throughout its prime mission. Cassini is instrumented with two magnetometers, a vector fluxgate and a helium magnetometer, the latter operated in a mode to measure field magnitudes near the planet (Dougherty et al., 2004). However, a large number of orbits have been executed thus far, many with periapsides $<4R_s$. The spacecraft is just now executing a series of maneuvers designed to increase the inclination of the orbit, which will provide a more favorable distribution of observations for internal field analysis, particularly near the end of mission, with many orbits planned with periapsides $<3R_s$.

10.06.4.2.2 Models

The Pioneer 11 magnetic field observations were consistent with a dipole field of moment ~0.20 G-R_s^3, slightly offset to the north of the planet's center (Acuña and Ness, 1980; Acuña et al., 1980; Smith et al., 1980a) by about 0.04 or $0.05R_s$. The simple northward-offset dipole model was affirmed by independent analyses of charged particle absorption signatures (Chenette and Davis, 1982), which serve as a probe of the geometry of the field. Analyses of the Pioneer 11 high-field FGM observations (Acuña et al., 1980) found no departure of the field from axisymmetry; however, in Saturn's relatively weak field, the resolution of the high-field fluxgate was quite limited. Working with higher-resolution VHM observations, Smith et al. (1980b) proposed a dipole tilt of $\sim 1^\circ$, although the orientation of the dipole could not be determined.

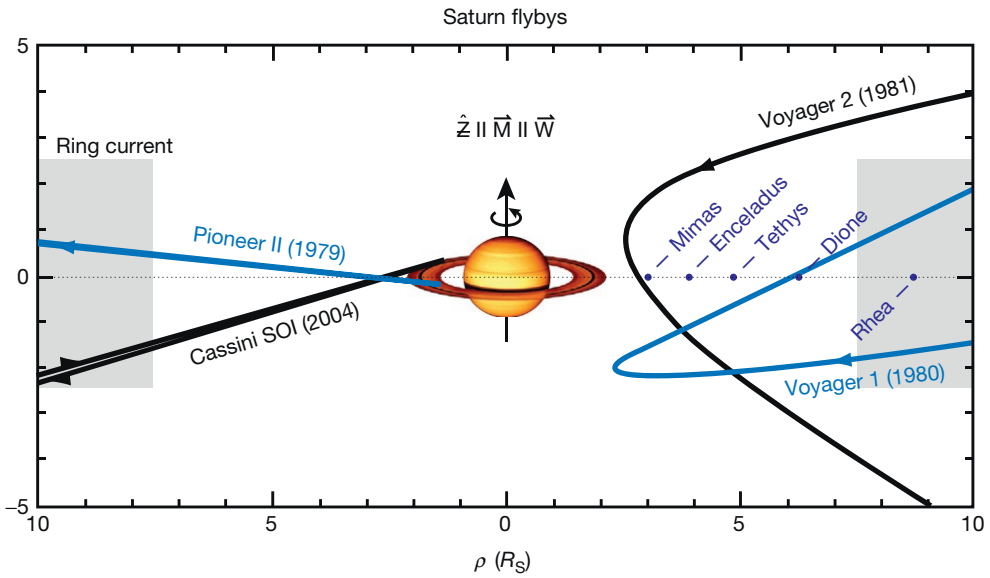

Figure 16 Spacecraft flybys (Pioneer 11, Voyager 1 and 2, and Cassini) of Saturn in a cylindrical coordinate system in which the z-axis is aligned with Saturn's magnetic dipole axis and rotation axis. The spacecraft distance from the equator plane (z) as a function of distance from the z-axis (ρ) is given in units of Saturn radius. The positions of satellites Mimas, Enceladus, Tethys, Dione, and Rhea are indicated. The shaded region approximates the innermost portion of a washer-shaped region of azimuthal ring currents.

The combined Voyager 1 and 2 magnetic field observations were not consistent with the field of a simple displaced dipole, nor did these observations reveal any measurable departure from spin axisymmetry (of the internal field). An axisymmetric, zonal harmonic model of degree 3 was found to be both necessary and sufficient to describe the magnetic field of Saturn (Connerney et al., 1982b). This three-parameter model is referred to as the Z_3 model (zonal harmonic of degree 3) and it is listed in **Table 4**; the nonaxisymmetric terms ($m>0$) are insignificant. Independent analyses of the Voyager 1 and 2 observations suggested an estimated uncertainty of ~100 nT for the Z_3 coefficients. This is perhaps the best way to estimate errors when model residuals are highly correlated – a comparison of independent analyses, using separate flybys. The Z_3 model parameter uncertainties are likely to be smaller, benefiting from the combined observations of both Voyager flybys. The magnetic and rotation axes are indistinguishable, aligned to within ~0.1°.

A series of analyses followed to test the high degree of axisymmetry of the Z_3 model (reviewed in Connerney et al. (1984b)). Acuña et al. (1983a) showed that the charged particle absorption signatures observed in Saturn's magnetosphere were consistent with the Z_3 model. A reanalysis of the absorption signatures studied by Chenette and Davis (1982), allowing for the presence of a nonzero g_3^0 term, found these signatures to be best fit by a zonal harmonic model that was indistinguishable from the Z_3 model (Connerney et al., 1984b). A reanalysis of the Pioneer 11 VHM observations (Connerney et al., 1984a) identified a spacecraft roll attitude error (of 1.4° in magnitude) as the primary source of the discrepancy between the Pioneer 11 and the Voyager results. After correcting the spacecraft roll attitude, these authors demonstrated that the Pioneer 11 VHM measurements were consistent with the Z_3 model field, and axisymmetry, to better than the accuracy of measurement (Connerney et al., 1984a). The roll attitude error was subsequently independently verified by the analysis of Pioneer 11 imaging photopolarimeter data. After correcting for the Pioneer 11 roll attitude error, Davis and Smith (1985, 1986) combined the Pioneer 11 VHM and Voyager magnetometer observations and obtained a zonal harmonic model Saturn Pioneer Voyager (SPV) in substantial agreement with the Z_3 model (**Table 4**).

Table 4 Saturn magnetic field models

	Cassini	*Voyager*			*Pioneer 11, Voyagers 1 and 2*

G_1^1		−1	0	−1	( )
H_1^1		0	0	−2	( )

Schmidt normalized zonal harmonic coefficients in nT, SLS coordinate system: $1R_s = 60\,330$ km for Voyager and Pioneer 11 models. Cassini SOI uses $1R_s = 60\,268$ km. Voyager and Pioneer models provided in this table have been adjusted for a reference radius of 60 330 km; see Connerney et al., 1982b for coefficients referenced to 60 000 km radius as originally published. The SPV model (Davis and Smith, 1990) used Pioneer 11 observations corrected for a roll attitude error (Connerney et al., 1984a) in combination with Voyager observations. SPV used different external (uniform) fields for each encounter.

Analysis of the Cassini FGM observations obtained during SOI confirmed (to the level of estimated measurement accuracy, ~0.1% and 0.1°) the spin symmetry of Saturn's magnetic field (Dougherty et al., 2005). An unfortunate command error prevented the helium magnetometer from making measurements of the field magnitude during SOI. A zonal harmonic model of degree 3 was obtained (**Table 4**) from the fluxgate observations; it is very similar to the earlier zonal harmonic models derived from Voyager and Pioneer observations but for a smaller g_3^0 term. **Figure 17**, in which we plot the vector magnetic field observed throughout Cassini's orbit insertion maneuver, illustrates the remarkable spin symmetry of Saturn's internal field. The absence of a significant azimuthal field component during this close encounter suggests a negligible tilt of the dipole and the lack of higher-order contributions to the field.

More revealing, perhaps, is **Figure 18**, which plots the vector residual after the best-fitting zonal harmonic model has been removed from the observations. Residuals that *are* observed can be understood by attention to engineering practicalities, for example, spacecraft attitude maneuvers associated with turns to avoid impact of ring material on sensitive components ('turn turtle,' i.e., assume a protected attitude crossing the ring plane) and the Earth point maneuver. Errors in the measured vector magnetic field can arise from attitude uncertainties associated with spacecraft maneuvers or with variations in sensor response as the field direction in the sensor reference frame changes. A turning spacecraft often depends on gyros for attitude information, lacking a celestial reference, and slight errors in gyro drift rates may result in attitude errors during maneuvers. Likewise, one sees an increase in variations of the field associated with the main engine burn and its aftermath. This figure also illustrates that the residuals are highly correlated and dominated by systematic effects, most of which can be readily understood and related to spacecraft engineering events; thus, estimates of model parameter uncertainties based on propagation of errors and Gaussian statistics are likely to be overly optimistic.

Near the end of Cassini's prime mission, a number of orbits were acquired with periapsides inside the orbit of Enceladus ($3.95R_s$), providing much-needed close-in observations at higher latitudes (though still within about ±30° of the equator). More recent modeling efforts have assembled a large number of orbits obtained over a lengthy span of time, fitting zonal harmonic internal fields with external fields described by external spherical harmonics or an explicit ring current (or magnetodisk) model. These models are listed in **Table 5**. Burton et al. (2009) analyzed observations (45 individual orbits) acquired during Cassini's first 3 years (July 2004–2007) utilizing an explicit ring current model to represent external fields. They found no departure from axisymmetry in the internal field and little evidence for secular variation of the field over the 30 years between the Pioneer/Voyager era and the Cassini era. A later study by the same authors (Burton et al., 2010) used observations confined to the region inside the orbit

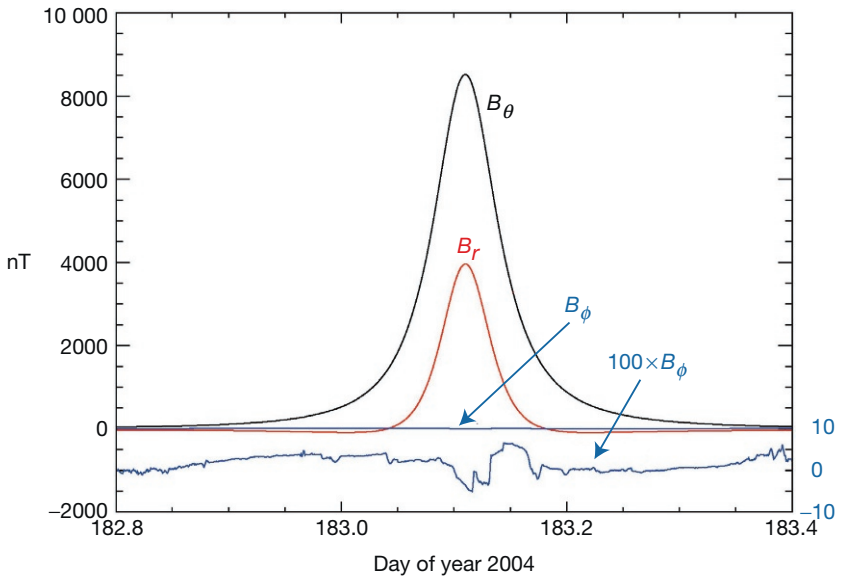

Figure 17 Vector magnetic field observed during Cassini Saturn Orbit Insertion (SOI) on day 183, 2004. The observed field is dominated by the smooth variation of the radial (red) and theta (black) components of the field. The azimuthal component of the magnetic field (blue) is very small throughout the equatorial passage and is plotted again increased by a factor of 100 and offset by 10 nT for clarity.

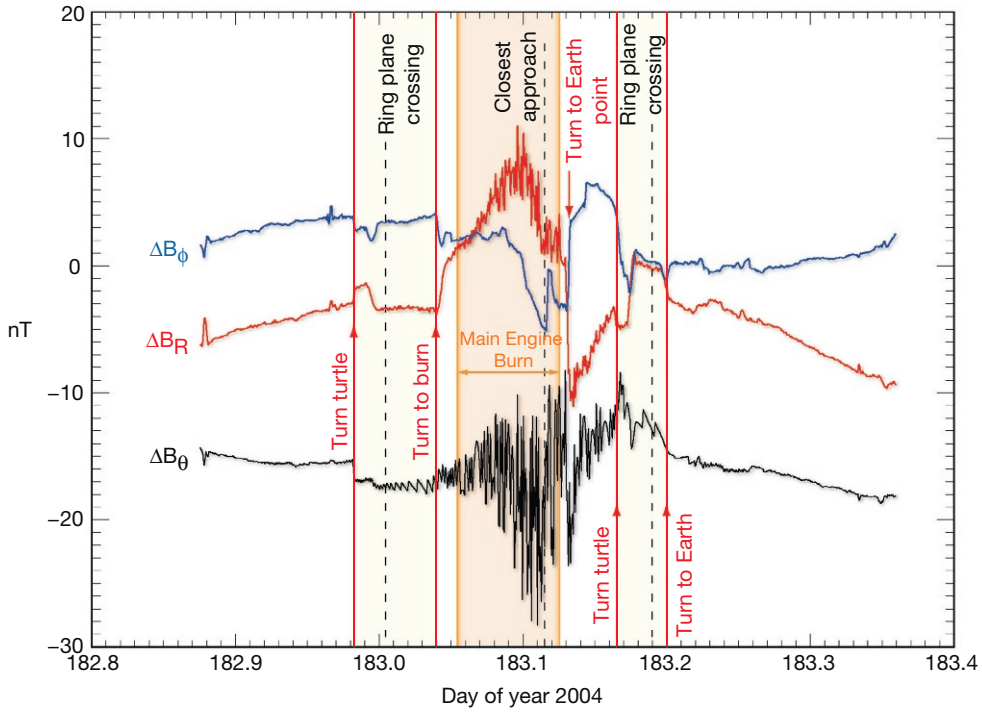

Figure 18 Vector residual magnetic field during the Cassini Saturn Orbit Insertion on day 183, 2004. The best-fitting zonal harmonic (axisymmetric) model of Saturn's planetary magnetic field has been removed from the observations, and the components of the residual field have been plotted as a function of time. The radial and theta components are offset (by 10 and 20 nT, respectively) for clarity. Significant spacecraft maneuvers and events are indicated. Systematic differences between the best-fitting zonal harmonic model and the observed field are evident; the residuals in all three components are clearly associated with spacecraft turns and propulsive events.

of Enceladus at $3.95R_s$ (to mitigate external effects) and represented external fields with a spherical harmonic expansion, reaching the same conclusions listed earlier. The latter study also explored a range of putative Saturn rotation periods, finding no preference for a different rotation rate and no significant nonaxial internal field. Likewise, Cao et al. (2011) modeled observations obtained over a span of 5 years within the Enceladus L-shell, using a simple uniform external field

representation. They also found that a zonal harmonic internal field of degree three is sufficient to describe Saturn's magnetic field. They arrived at a reduced upper limit for the tilt of the dipole ($<0.06°$). Their more recent reanalysis of the Cassini SOI observations (Cao et al., 2012) – fixing the zonal harmonics with degrees 1–3 and performing a Monte Carlo search for a best-fitting g_4^0 and g_5^0 – resulted in the identification of nonzero fourth- and fifth-degree zonal harmonic terms. These are both very small in magnitude, however, and not much larger than the estimated parameter uncertainties (which are likely to be quite optimistic; see, e.g., **Figure 18**).

Cassini, in its extended 'Solstice' mission, now enters a phase in which the orbital inclination increases, providing close-in observations of the magnetic field at progressively higher latitudes. With better spatial coverage, and as more observations accumulate, one may expect some refinement of the spherical harmonic models derived from Cassini.

10.06.4.2.3 Discussion

Magnetic field magnitudes (Z_3 model) on the surface of a dynamically flattened Saturn (flattening 1/10.6) range from a minimum of 0.18 G at the equator to maxima of 0.65 and 0.84 G at the southern and northern poles, respectively (**Figure 19**). Note that Saturn is the most dynamically flattened of all the planets, and the polar magnetic field is substantially increased by the decreased radial distance ($0.9R_s$) at the poles. The equatorial field magnitude is less than that of a simple dipole or offset dipole, and polar field magnitudes (both north and south) exceed those of either a centered or an offset dipole. An eccentric dipole representation of the Z_3 model has a northward displacement of the dipole of $0.038R_s$ along the rotation axis (Connerney, 1993), in agreement with the Pioneer 11 OTD representations. However, the ratio of g_3^0/g_2^0 is too large by a factor of 30 to be attributed to a dipole offset. The Z_3 model's large antisymmetry with respect to the equator plane cannot be removed by a simple coordinate system translation. The same can be said of all of the Saturn zonal harmonic models listed in **Tables 4** and **5**.

The high degree of spin axisymmetry of Saturn's magnetic field is unique among the planets. This unanticipated symmetry is somewhat disquieting from an observational perspective, as it lends no simple explanation for observations of periodic magnetospheric phenomena, for example, periodicities in magnetic field and particle observations in the distant magnetosphere (Connerney and Desch, 1992; Cowley et al., 2006; Galopeau et al., 1991; Giampieri and Dougherty, 2004; Giampieri et al., 2006; see also Kaiser et al., 2005 and Giampieri et al., 2005), the modulation of Saturn kilometric radio emission (Desch and Kaiser, 1981; Kaiser and Desch, 1982), optical spoke activity in Saturn's B ring (Porco and Danielson, 1982), and ultraviolet auroras (Sandel et al., 1982). All of these phenomena would presumably be easier to explain if a magnetic anomaly could be found. However, it is not clear how such a slight departure (e.g., near the $\sim 0.1°$ limit of detection) from axisymmetry might so

Table 5 Saturn Cassini orbiter magnetic field models

	Cao et al. (2011)	*Burton et al. (2010)*	*Burton et al. (2009)*

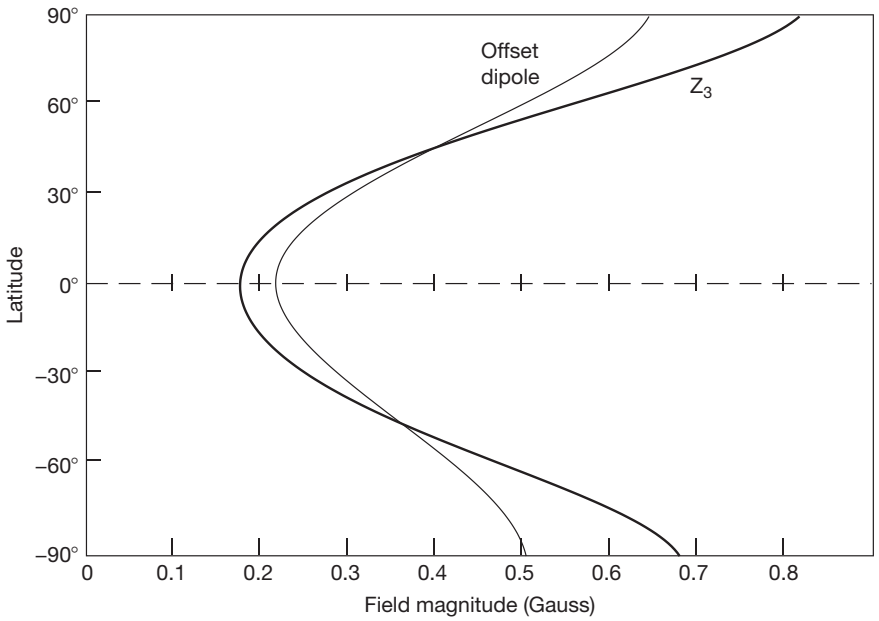

Figure 19 Magnetic field magnitude (Gauss) as a function of planetocentric latitude on the dynamically flattened (1/10.6) surface of Saturn computed using the axisymmetric Z_3 (zonal harmonic of degree 3) model of Saturn's magnetic field (Connerney et al., 1982b), compared with that of a simple offset dipole.

dramatically influence these phenomena, which occur at different magnetic latitudes and as far as 1 or $2R_s$ above the surface.

The uncertainty regarding the origin of Saturn's quasi-periodic magnetospheric phenomena has spilled over into a related topic: Saturn's rotation period. Accurate measurement of the rotation period of gaseous planets relies on the long-term observation of magnetospheric radio emissions, which are assumed to be locked in phase with the magnetic field and interior of the planet. Long-term observation of Jupiter's radio emissions, for example, yield a consistent estimate (Riddle and Warwick, 1976) of rotation period (9 h, 55 m, 29.71 s) regardless of frequency of emission measured or method of analysis (Carr et al., 1983). Note that the uncertainty associated with this estimate is about 0.02 s (Carr et al., 1983), reflecting observation over many years. Saturn's rotation period was measured in the Voyager era (1980–81) using periodicities in kilometric radio emissions (SKR), yielding an estimate of the rotation period (10 h, 39 m, 24 s) with an uncertainty of ± 7 s (Desch and Kaiser, 1981; Kaiser et al., 1984). The larger uncertainty of this estimate is due to the limited span of time (9 months) over which SKR could be monitored. Continued observation of Saturn's radio emissions, however, in the Ulysses era (Gurnett et al., 2005) and during the Cassini mission (Gurnett et al., 2006, 2007; Kurth et al., 2007) revealed variations of about $\pm 1\%$ ($\sim$6 min) in the apparent radio period – far in excess of that allowed by statistical uncertainties. Likewise, direct measurement of periodicities in the magnetic field (Giampieri and Dougherty, 2004; see also Cowley et al., 2006; Giampieri et al., 2005, 2006; Kaiser et al., 2005) yielded inconsistent rotation periods, at best, with little promise of establishing a true rotation rate (Sterenborg and Bloxham, 2010).

Saturn's radio emissions are influenced by variations in the solar wind (Desch, 1982; Desch and Rucker, 1983) and are emitted from a source region fixed in local time (Galopeau et al., 1995; Kaiser and Desch, 1982; Kaiser et al., 1984). It has thus been proposed that variations in the apparent periodicity of radio emissions are related to variations in the solar wind (Cecconi and Zarka, 2005). Gurnett et al. (2007) observed that the SKR period derived from Cassini radio observations differed substantially from that deduced from the Voyagers; even worse, the SKR-derived period was found to be anything but constant in time (Gurnett et al., 2007). Thus, it is not clear which of the proposed rotation periods, if any, closely match that of the deep interior of the planet.

Not surprisingly, then, interest has turned to other means of establishing Saturn's rotation period and even questioning what it means to assign such a number to a fluid planet (Stevenson, 2006). The Voyager era rotation period was never warmly embraced among atmospheric scientists because this period results in an atmosphere that superrotates at nearly all latitudes (Melendo et al., 2011; Smith et al., 1982). In contrast, Jupiter's atmosphere is characterized by alternating eastward and westward jets, referenced to its system III (radio) period. Thus, a number of proposals have emerged that would have Saturn rotating significantly faster. Anderson and Schubert (2007) treated Saturn's rotation period as a free variable and found the period (10 h, 32 m, 35 ± 13 s) that best reconciles gravity, radio occultation, and wind observations; they proposed this as a more accurate period of rotation of Saturn's interior. The validity of this method is somewhat bolstered by application to Jupiter (Helled et al., 2009), where it results in a period that agrees well with the radio-derived period. A similar Saturn rotation period (10 h, 34 m, 13 ± 20 s) is obtained from a consideration of atmospheric dynamic stability (Read et al., 2009; see also Showman, 2009). Either proposal results in a more Jupiter-like system of eastward- and westward-flowing jets that would be expected of a giant planet with a water-rich atmosphere driven by large-scale latent heating (Lian and Showman, 2010).

This is the subject of intense activity at present, so perhaps, a better understanding of Saturn's rotation will be forthcoming soon. An accurate value for the rotation period is essential to arriving at an understanding of Saturn's interior structure and composition.

The magnetic fields of Earth, Jupiter, and Mercury all favor dipole tilts of $\sim 10^\circ$ in magnitude; Saturn's dipole tilt is not yet determined but $<0.06^\circ$ or so. The high degree of spin axisymmetry is surprising but not in and of itself a problem for dynamo theory (e.g., Lortz, 1972). The Cowling antidynamo theorem (Cowling, 1937, 1957), which states that regenerative dynamo action cannot occur if the magnetic field and fluid motions are axisymmetric, applies to the field in the dynamo region, not the field observed above. It is, however, necessary to explain why Saturn's magnetic field is so dramatically different from Jupiter's, given the similarity in size, composition, and rotation.

Stevenson proposed a model in which the field is axisymmetrized by the differential rotation of an electrically conducting shell above the dynamo region (Stevenson, 1980, 1982; also Kirk and Stevenson, 1987). This nonconvecting shell forms above the dynamo region as a result of the immiscibility of helium and hydrogen under the temperature and pressure conditions in this region (the larger planet, Jupiter, would have no such region). In this model, the formation of helium raindrops results in a stably stratified conducting shell which, in differential rotation with respect to the core, attenuates any nonaxisymmetric fields generated below. Schubert et al. (2004) treated the more general case of dynamo generation in a convective core within an electrically conducting shell, taking into account the mutual coupling between the two. These authors concluded that the observable characteristics of planetary dynamos are largely determined by the nature of the (electrically conducting) flow above the dynamo region. That is to say, the mere presence of a stably stratified, conducting shell in differential rotation above the dynamo is not sufficient to axisymmetrize the field (Stanley and Mohammadi, 2008); but it may act to axisymmetrize the field if it is sustained by a thermal wind as a result of a pole-to-equator temperature difference (Christensen and Wicht, 2008; Stanley, 2010). The dynamo models studied thus far do not go quite far enough in axisymmetrizing the field, producing dipoles with 1–2° angular separation between magnetic and spin axes, compared to Saturn's $<0.1^\circ$ dipole tilt.

The Z_3 model of Saturn's field can be used (with caution) to predict the field inside the planet but above the dynamo (or regions of current flow). The radial field component is of particular interest since it is continuous across the core boundary and, if the frozen flux assumption is satisfied, serves as a tracer of horizontal fluid motion at the outer radius of the dynamo (Backus, 1968; Benton, 1979; Benton and Muth, 1979). **Figure 20** shows the latitudinal variation of $|B_r|$,

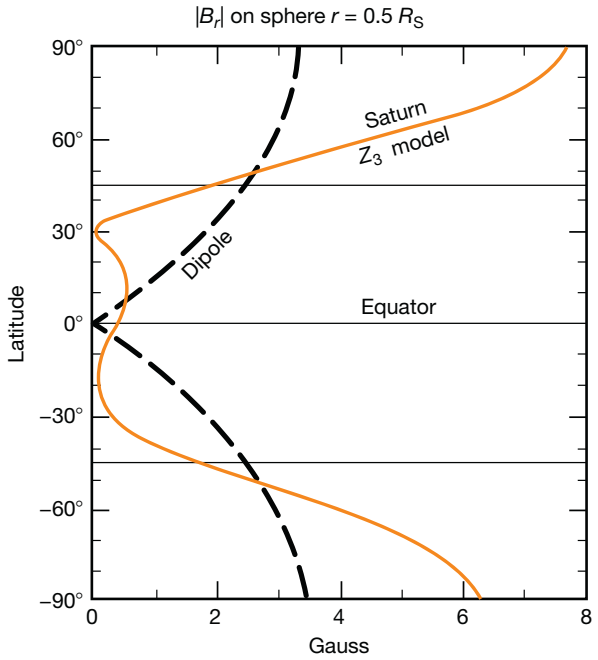

Figure 20 Unsigned magnetic flux computed on a sphere of radius 0.5 R_s (presumed dynamo core radius) using the Z_3 magnetic field model, compared to that for a simple dipole. Saturn's magnetic field is very nearly identical to that that (with three terms) minimizes the low-latitude (<45°) unsigned magnetic flux across the core boundary. Reproduced from Connerney JEP (1993). Magnetic fields of the outer planets. *Journal of Geophysical Research* 98(E10): 18659–18679.

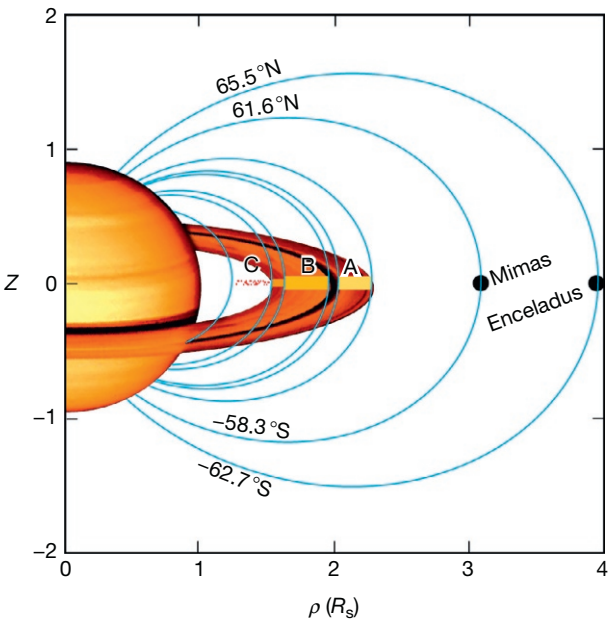

Figure 21 Saturn's magnetic field is very nearly symmetrical about its rotation axis but not about the equator. All field lines passing through the ionosphere at one latitude cross the ring plane at a unique radial distance (ring plane conjugate) and map to a corresponding (but different) latitude in the opposite hemisphere. The magnetic equator is at 5.9° N (planetocentric) latitude. Reproduced from Connerney JEP (1986) Magnetic connection for Saturn's rings and atmosphere. *Journal of Geophysical Research* 13(8): 773–776.

computed using the Z_3 model, on the surface of a sphere of radius $r = 0.5R_s$, which is the approximate outer boundary of the metallically conducting core (Stevenson, 1983). The Z_3 model (via the g_3^0 term) enhances the field at the poles and reduces the radial field near the equator, relative to a simple dipole. In fact, the Z_3 model is very nearly identical to that required to minimize the low-latitude unsigned flux across the core surface (Connerney, 1993). Cao et al. (2012) reached a similar conclusion with their preferred zonal harmonic model, albeit with a dynamo core radius ($0.4R_s$) that is significantly smaller than the radius ($0.64\ R_s$) of metallically conductive hydrogen (Weir et al., 1996). The concentration of radial flux at the spin poles, and minimization of radial flux at low latitudes, may be the signature of a dynamo axisymmetrized by differential rotation of a conductive layer above.

The high degree of symmetry (about the rotation axis) of Saturn's magnetic field is a distinguishing feature that may have some unexpected consequences throughout the system. For this planet, a specific radial distance in the equatorial plane maps (along the magnetic field) uniquely to a corresponding latitude on the surface (Connerney, 1986), as is illustrated in Figure 21. Thus, one may associate a radial distance (ring plane conjugate) with any northern or southern latitude. From a practical standpoint, all of the zonal harmonic models introduced subsequent to the Z_3 model yield a very similar mapping from equator to ionosphere. Narrow dark bands that encircle the planet at 44.2°, 46.3°, and 65.5° N have been attributed (Connerney, 1986) to an influx of water guided along magnetic field lines from sources in the ring plane: two locations at the inner edge of the B ring ($1.525R_s$, $1.62R_s$) where high-charge-to-mass-ratio particles (e.g., submicron ice or dust) become unstable (Northrop and Connerney, 1987) and a third ($3.95R_s$) at the orbit of Enceladus and the E ring. The B-ring sources are identified with an electromagnetic erosion mechanism that sculpted the rings (Northrop and Connerney, 1987), a process that over tens of millions of years removed most of the mass from the C ring, for example. Recent Keck observations of H_3^+ emissions from Saturn's ionosphere (O'Donoghue et al., 2013) reveal a latitudinal variation in ion density that suggests transport of water in the form of high-charge-to-mass-ratio particles along magnetic field lines from sources in the rings (Connerney, 2013). The Enceladus/E-ring source may reflect persistent activity of the recently discovered geysers on Enceladus (Kargel, 2006; Kivelson, 2006).

10.06.5 Ice Giants

10.06.5.1 Uranus

Uranus, residing at a mean orbital distance of 19.2 AU, was a mystery prior to the Voyager 2 encounter with Uranus in January 1986. The planet appears bland and featureless when observed from the Earth even under the best circumstances. Uranus and Neptune are similar in size (~25 000 km radius), mass (about 15 Earth masses), and presumably composition (largely low-temperature condensates or 'ice': H_2O, NH_3, and CH_4). One might therefore expect that their magnetic fields would be similar. Uranus is unique in that its rotation axis lies

very near in its orbital plane, which is within 1° of the ecliptic plane. The actual inclination of its equatorial plane to that of its orbit is 82°. Twice during each orbit about the Sun (84 years), the rotation axis is oriented very near along the planet–Sun line, so that we on Earth look upon the pole. This was the case during the Voyager 2 encounter in 1986; the southern hemisphere was directed toward the Sun.

Uranus was not known to have a magnetic field prior to the Voyager encounter, having maintained 'radio silence' prior to encounter. It is a relatively weak radio source, emitting only at lower frequencies (below about 1 MHz), making detection from Earth difficult. In addition, the peculiar 'pole-on' encounter geometry kept the Voyager spacecraft beyond the reach of radio emissions. Voyager 2, on a flyby trajectory (**Figure 22**) approaching to within $4.2R_u$, provided the first and thus far only measurements of the magnetic field (Ness et al., 1986). These measurements led to the rather surprising discovery of the first 'oblique rotator,' a planet with a large angular separation between magnetic and rotation axes.

10.06.5.1.1 Models

Preliminary analyses of the Voyager magnetic field observations used an OTD representation of the field. This model is characterized by a dipole of moment 0.23 G R_u^3 ($1R_u = 25\,600$ km), displaced along the rotation axis by $0.33R_u$ and inclined by 60° with respect to the rotation axis (Ness et al., 1986). Since Voyager remained somewhat distant, an OTD representation is expected to be a good approximation to the field, and indeed, it fits the observations well (Ness et al., 1986). The very large dipole offset of the OTD is an indication of a planetary magnetic field with a large quadrupole and likely higher-degree and higher-order terms, that is, a very complex field.

A spherical harmonic analysis of the field required an expansion to degree and order 3 (octupole) to adequately represent the measurements (Connerney et al., 1987), which is somewhat surprising in view of Voyager's relatively large periapsis ($4.2R_u$). The Voyager trajectory provided a fairly good spatial distribution of observations, sufficient to resolve, or determine, spherical harmonic terms of degrees 1 and 2, the dipole and quadrupole. This partial solution to the underdetermined inverse problem, designated 'Q_3' (quadrupole part of an expansion to degree and order 3), is listed in **Table 6**. The relative magnitude of the quadrupole is quite large; the octupole is likely to be large as well, but cannot be meaningfully constrained by the observations alone. Holme and Bloxham (1996) obtained octupole coefficients utilizing a regularization technique that imposes a smoothness constraint on the field; the resulting model is quite similar to that obtained by Connerney et al. (1987) among the lower-degree coefficients and presents a plausible extension of the model field to higher degree and order. Lack of knowledge of higher-degree and higher-order terms may be an important consideration, particularly in estimation of the field near the planet. The Q_3 model was extended to higher degree and order using the mapped location of near-surface ultraviolet auroral emissions that were assumed to lie on conjugate L-shells (Herbert, 2009). The Q_3 model provides a low-degree and low-order approximation only, and it is likely that surface fields are more complex than illustrated here.

The magnetic field magnitude on the surface of Uranus reaches a maximum of ~1 G at midlatitudes in the south and

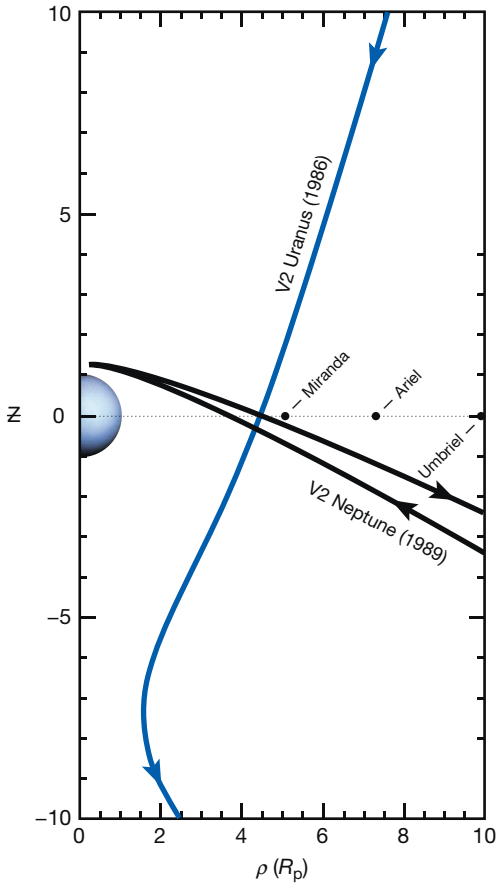

Figure 22 Voyager 2 spacecraft flybys of Uranus and Neptune in a cylindrical coordinate system. The spacecraft distance from the equator plane (z) as a function of distance from the rotation axis (ρ) is given in units of planet radius. The positions of satellites Miranda, Ariel, and Umbriel in the Uranus system are indicated.

Table 6 Uranus magnetic field models

		Connerney et al. (1987)	*Holme and Bloxham (1996)*
Coefficient		*Uranus* Q_3	*Uranus*
1	g_1^0	11893.0	11855.0
2	g_1^1	11579.0	11507.0
3	h_1^1	−15689.0	−15812.0
4	g_2^0	−6030.0	−5877.0
5	g_2^1	−12587.0	−13085.0
6	g_2^2	196.0	−605.0
7	h_2^1	6116.0	5851.0
8	h_2^2	4759.0	4185.0
9	g_3^0		4183.0
10	g_3^1		−1336.0
11	g_3^2		−6776.0
12	g_3^3		−4021.0
13	h_3^1		−5817.0
14	h_3^2		−357.0
15	h_3^3		−2265.0

Spherical harmonic coefficients in nT; $1R_u = 25\,600$ km.

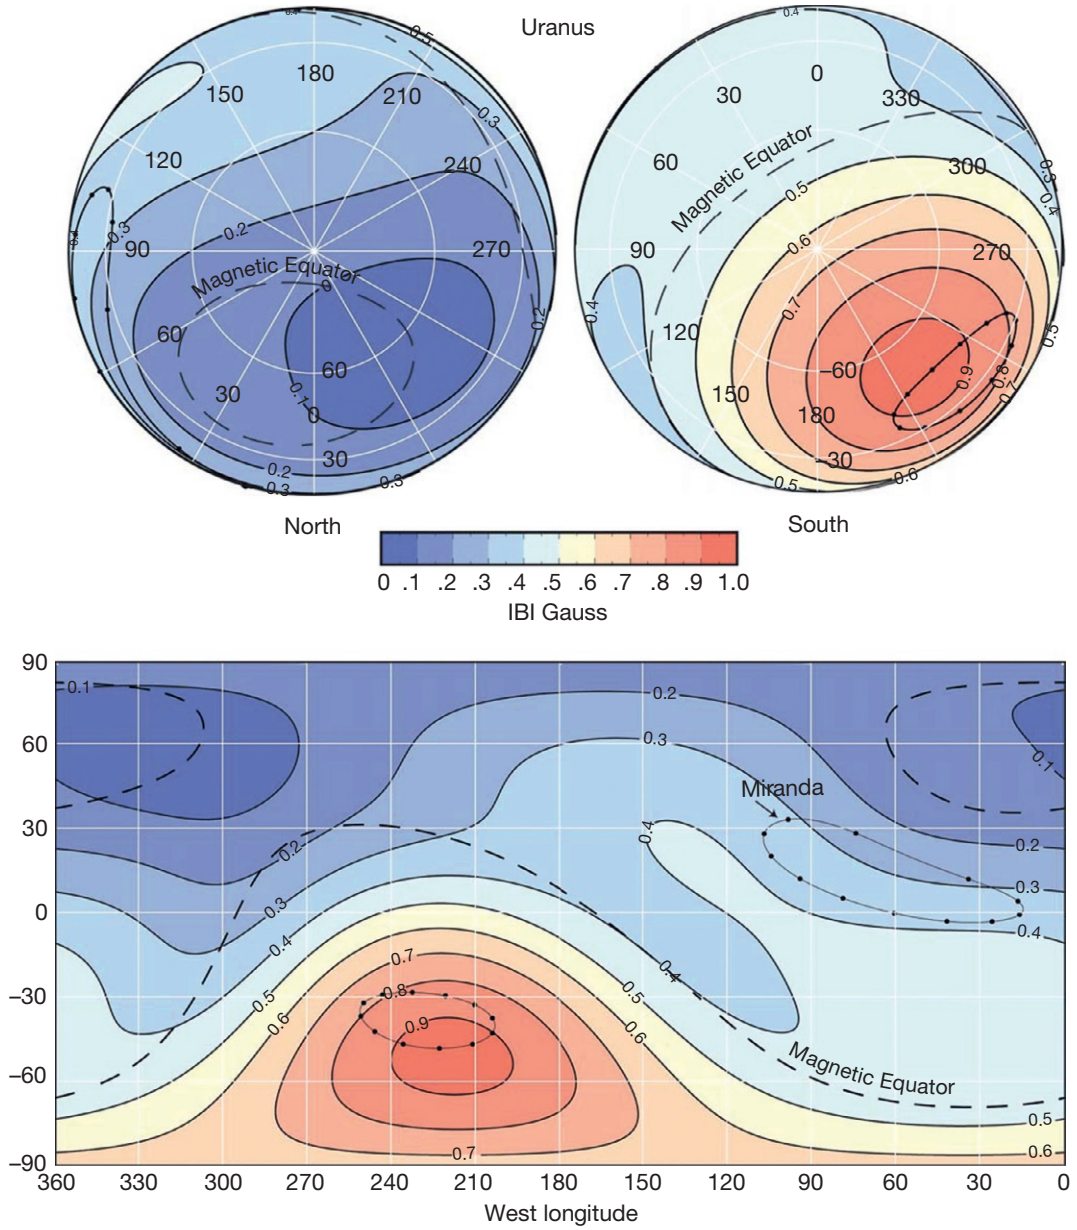

Figure 23 Contours of constant magnetic field magnitude (Gauss) on the dynamically flattened (1/41.6) surface of Uranus, computed using the Q_3 spherical harmonic model (see text). The top panel shows the field magnitude in orthographic projections viewed from $+z$ (left) to $-z$ (right); below the color bar is a rectangular latitude–longitude (west longitude) projection. A trace (dashed) indicates the position of the magnetic equator. Solid lines join points on the surface that trace along field lines to the orbit of the satellite Miranda, with filled circles for increments of 30° in the satellite's longitude.

a minimum of ≤ 0.1 G at middle to high northern latitudes (Figure 23). Figure 23 also illustrates the foot of the Miranda flux tube, which is the path traced out on the planet's surface by the field lines passing through the satellite as the planet rotates. Also shown are estimates of the position of the auroras (stippled regions) and the paths of multiple-dip equators (where $B_r = 0$). Uncertainties in the higher-degree and higher-order components of the field, which are substantial, may lead to large differences in the actual surface field, particularly in the weaker field regions. Note that for Uranus, the convention adopted by the Voyager particles and fields investigations is at odds with the International Astronomical Union (IAU) latitude convention. The Voyager system has planetary latitudes positive over the hemisphere in which the angular momentum vector resides, that is, the hemisphere oriented toward the Sun (and Earth) at the time of the Voyager encounter. The IAU defines the south pole as the rotation pole south of the ecliptic, without regard to the direction of rotation.

10.06.5.2 Neptune

Neptune, residing at a mean orbital distance of 30 AU, is the most distant of the Jovian planets. It is similar in size (~25 000 km radius), mass (about 15 Earth masses), and

composition (largely low-temperature condensates or 'ice': H_2O, NH_3, and CH_4) to Uranus. Very little was known of Neptune prior to the Voyager 2 encounter in August 1989. The first evidence of Neptune's magnetic field appeared in radio observations (Warwick et al., 1989) obtained by Voyager 2 just days prior to its closest approach to the planet on 25 August 1989.

The *in situ* magnetic field observations revealed a magnetic field of internal origin with characteristics not unlike those of the planet Uranus (Ness et al., 1989). The most striking difference between the Uranus and the Neptune encounters was a difference of our own design: the Voyager 2 flyby trajectories at each planet. Where Voyager 2 at Uranus remained relatively distant from the planet, Voyager 2 at Neptune approached to within $1.18R_n$ of the planet (**Figure 22**). The presence of higher-degree and higher-order components of the field in the latter observations is overwhelming, simply a consequence of the close periapsis. Preliminary analyses of the Voyager magnetic field observations used an OTD representation of the field, valid at moderate distances from the planet (4–15R_n radial distance; $1R_n = 24\,765$ km), and fitted to data in excess of $4R_n$ from the planet only. In this first approximation, the field may be characterized as that of a dipole of moment 0.13 G R_n^3, offset from the center of the planet by a rather surprisingly large $0.55R_n$ and inclined by 47° with respect to the rotation axis (Ness et al., 1989).

10.06.5.2.1 Models

It was necessary for Ness et al. (1989) to exclude from their OTD analysis all observations of the field obtained at $r \leq 4R_n$. One indication of how nondipolar the field of Neptune is can be had by comparison of the actual field measured at closest approach (~10 000 nT) to that one would expect if the field were dipolar (6500 nT, for the OTD model). In fact, the field measured near closest approach was quite complex, as is illustrated in **Figure 24**. Two local maxima appear in the magnitude of the field observed along the flyby trajectory, instead of the one maximum one would observe in a dipolar field. Spherical harmonic analysis of the field required an expansion to degree and order 8 to adequately represent the measurements (Connerney et al., 1991). The large number of parameters associated with a spherical harmonic expansion of degree and order 8 (80 Schmidt coefficients) and the rather limited observations lead to a severely underdetermined inverse problem that has only a partial solution (Connerney et al., 1991). The distribution of observations is sufficient to resolve, or determine, all of the spherical harmonic terms of degree 1 (dipole), some of the terms of degree 2 (quadrupole), and some terms of degree 3 (octupole) and higher. The resulting model, designated 'O_8' (octupole part of an expansion to degree and order 8), is listed in **Table 7**. For the Neptune field model, it is necessary to add a measure of the resolution of each parameter listed in **Table 7**. For this, we use the magnitude of the corresponding diagonal element of the resolution matrix, a measure of the uniqueness of the solution, the extent to which an individual model parameter can be represented by the basis vectors included in the partial solution. Note that some of the quadrupole and octupole coefficients of the O_8 model are not well resolved, but included out of necessity (see discussion of parameter resolution in Connerney et al. (1991)).

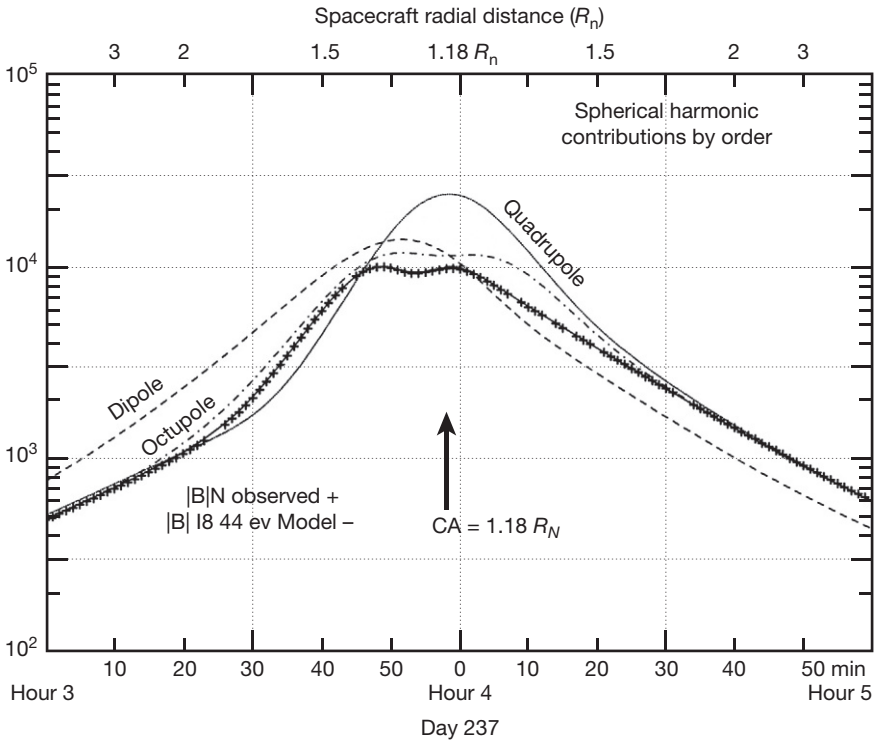

Figure 24 Magnitude of the observed magnetic field (crosses) as a function of time (lower axis) and spacecraft radial distance (upper axis) for the Voyager 2 encounter with Neptune, compared with a model fit (O_8 model) and the relative magnitudes of the dipole (dashed), quadrupole (solid), and octupole (dot-dashed) terms in the spherical harmonic expansion.

Table 7 Neptune magnetic field models

		Connerney et al. (1991)	*Holme and Bloxham (1996)*
Coefficients		*Neptune O_8*	*Neptune*
1	g_1^0	9732.0	10336.0
2	g_1^1	3220.0	3359.0
3	h_1^1	−9889.0	−9772.0
4	g_2^0	7448.0	8556.0
5	g_2^1	664.0	−406.0
6	g_2^2	4499.0	4644.0
7	h_2^1	11230.0	11139.0
8	h_2^2	−70.0	−743.0
9	g_3^0	−6592.0*	−5749.0
10	g_3^1	4098.0*	11632.0
11	g_3^2	−3581.0*	−1889.0
12	g_3^3	484.0	−2920.0
13	h_3^1	−3669.0	−3905.0
14	h_3^2	1791.0*	903.0
15	h_3^3	−770.0	−245.0

$1R_n = 24\,765$ km.
*Spherical harmonic coefficients in nT; coefficients that are *unresolved* are identified.

As anticipated, the relative magnitude of the quadrupole is quite large; the octupole is large as well, but can only be loosely constrained by the Voyager observations. The addition of a smoothness constraint (Holme and Bloxham, 1996) allows one to more confidently estimate the octupole coefficients, again resulting in a model that agrees well with the parameters in Connerney et al.'s (1991) model that are well resolved.

The magnetic field magnitude on the surface of the planet ranges from ~0.9 G at southern midlatitudes to ≤0.1 G near the equator and at northern midlatitudes (**Figure 25**). **Figure 25** also shows estimated auroral zones (stippled regions) that differ greatly in size as a result of the hemispherical asymmetry in field magnitudes. In this representation, it must be recognized that only the low-degree and low-order part of the field is portrayed on the surface of the planet, and the likely presence of higher-degree and higher-order terms may be expected to significantly alter the surface field. It is clear that the magnetic fields of Uranus and Neptune are quite similar in the range of surface field magnitudes, the tilt of the dipole, and the appearance of one strong pole at southern midlatitudes. Both Uranus and Neptune have extended weak-field regions, multiple-dip equators, and multipolar structure in evidence at the surface of the planet.

10.06.6 Satellites and Small Bodies

10.06.6.1 Moon

The Moon, with a radius of 1738 km and a mass of little more than 1% that of the Earth ($m/M_e = 0.0123$), is the largest satellite among the terrestrial planets. It is not so much smaller than Mercury (2439 km) in size, with a little more than one-third the volume of Mercury, but only about one-fifth of the mass. It is a differentiated object similar in composition to the Earth's mantle.

The Moon has been a frequent target of space exploration spanning nearly half a century, beginning with a series of robotic probes in the 1960s (Ranger series of the US space program and Luna and Zond series of the USSR program) and culminating in the first missions of human exploration of the Moon, the US Apollo program. For a brief moment in history, beginning with Apollo 11 on 20 July 1969, and ending with Apollo 17 on 14 December 1972, humans walked (and drove) on the surface of another world, deploying instruments and collecting soil and rock samples for return to Earth. Much of what we know of lunar magnetism evolved from study of the lunar samples returned from the Moon, combined with *in situ* observations collected both on the surface and in orbit about the Moon. Robotic scientific exploration of the Moon was rekindled decades after the Apollo program ended, beginning with the orbiting Clementine spacecraft in February and March of 1994. The Lunar Prospector (LP) spacecraft was in polar mapping orbit from 13 January 1998 to 31 July 1999, mapping crustal magnetic fields via both direct (magnetometry) and indirect (electron reflectometry) methods. Initially, LP operated in polar orbit at a nominal 100 km mapping altitude, followed by an extended mission (January–July of 1999) at reduced altitudes of between 15 and 45 km. ESA's SMART-1 spacecraft was in orbit about the Moon from 15 November 2004 to impact on 3 September 2006. In October 2007, Japan's SELENE spacecraft was inserted into an ~100 km altitude, polar mapping orbit to map crustal magnetic anomalies, characterize the lunar plasma environment, and probe its electrical conductivity structure (Tsunakawa et al., 2010). SELENE was a product of the ISAS and the National Space Development Agency (NASDA), both now part of the Japan Aerospace Exploration Agency (JAXA). After 20 months in orbit, SELENE impacted the lunar surface near the crater Gill, having completed its mapping mission.

The first complete lunar magnetic field map (**Figure 26**) to utilize the electron reflectometry method was compiled using 1.5×10^5 estimates of the surface field magnitude obtained over LP's 18-month mission (Mitchell et al., 2008). This map extends the electron reflection technique, correcting for charging of the lunar surface and spacecraft (Halekas et al., 2002), significantly improving the dynamic range of field magnitudes mapped relative to previous maps (Halekas et al., 2001). The surface field magnitude is estimated with a resolution of about 0.2 nT in magnitude. This map is still undersampled, in the sense that substantially more observations would be required to obtain complete spatial coverage at the resolution implied by the electron gyroradius (about 5 km at 300 eV). However, it provides a good sense of the global distribution of magnetic sources in the lunar crust, and it demonstrates that the characteristic scale length of coherent magnetization in the lunar crust is quite small. Where the lunar crust is magnetized, it is weakly magnetized (on spatial scales of 5 km and greater), compared to either the Mars' crust or Earth's. Lunar crustal magnetization also appears to be less coherent at large spatial scales, compared to Earth and Mars. The late, large impact basins (e.g., Orientale and Imbrium) appear nonmagnetic, implying that the impact melt cooled in zero field (no lunar dynamo at the time of impact); and yet, the regions of strongest field magnitude appear *antipodal* to the largest impact basins (Lin et al., 1988).

So it seems that lunar crustal magnetization and large impacts are related; perhaps impacts magnetize the crust not at the impact site, but on the opposite side of the Moon. One theory for how this might occur (Hood and Huang, 1991;

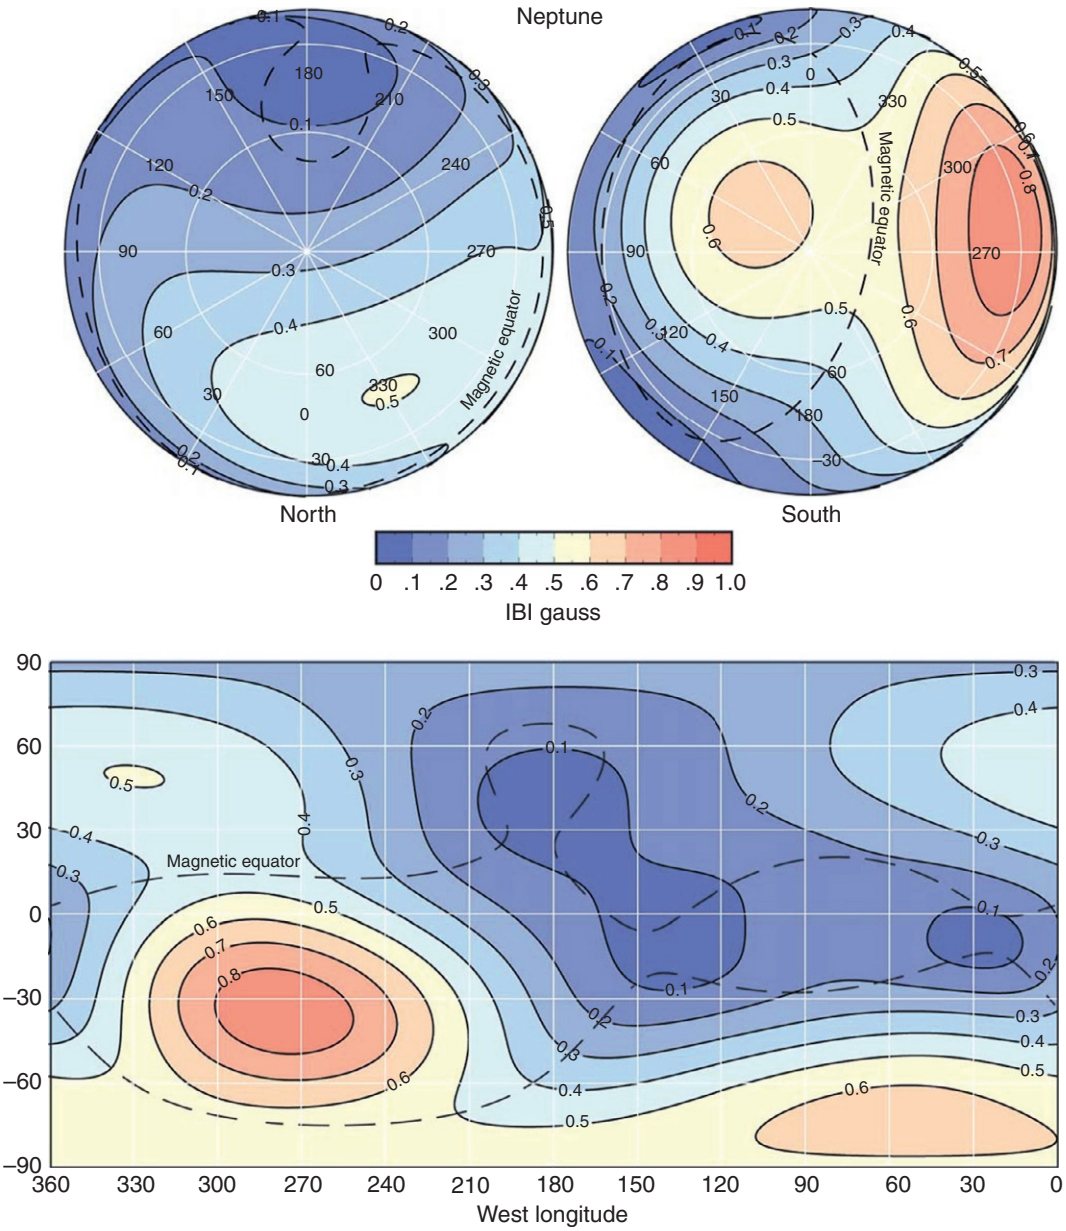

Figure 25 Contours of constant magnetic field magnitude (Gauss) on the dynamically flattened (1/47.6) surface of Neptune, computed using the O_8 spherical harmonic model (see text). The top panel shows the field magnitude in orthographic projections viewed from $+z$ (left) to $-z$ (right); below the color bar is a rectangular latitude–longitude (west longitude) projection. A trace (dashed) indicates the position of the magnetic equator.

Hood and Vickery, 1984) uses the impact-generated plasma cloud to intensify the weak ambient magnetic field at the antipode, if only briefly (~1 day), as it expands from the impact site to envelop the Moon. In this theory, the expanding plasma cloud, being a good electrical conductor, sweeps up the ambient field as it converges on the antipode, where the crust then acquires remanence via shock magnetization (Cisowski et al., 1983; Fuller et al., 1974). The efficacy of this process (the acquisition of remanence via shock in the presence of an applied magnetic field) has been demonstrated in shock experiments performed on lunar mare basalts (Gattacceca et al., 2010). Shock remanent magnetism (SRM) may be acquired by typical lunar rocks (dominated by multidomain iron–nickel mineralogy with low nickel content) subjected to low-pressure shocks (<10 GPa) attributed to lunar impacts. A detailed study of the magnetic field associated with multiring impact basins, estimated using the electron reflectometry technique, finds an extensive magnetic low of ~1.5–2 basin radii associated with each basin, attributed to shock demagnetization of the impact area (Halekas et al., 2003). A subset of these impact basins formed in the early Nectarian era (~3.9 Ga) also evidence a more compact, central magnetic high that is attributed to thermal remanence (TRM) in an ambient field, that is, evidence for a lunar dynamo operating at that time. The lack of such features in younger (Imbrian) impact basins (~3.2–3.85 Ga) and older (pre-Nectarian) impact basins (>3.92 Ga)

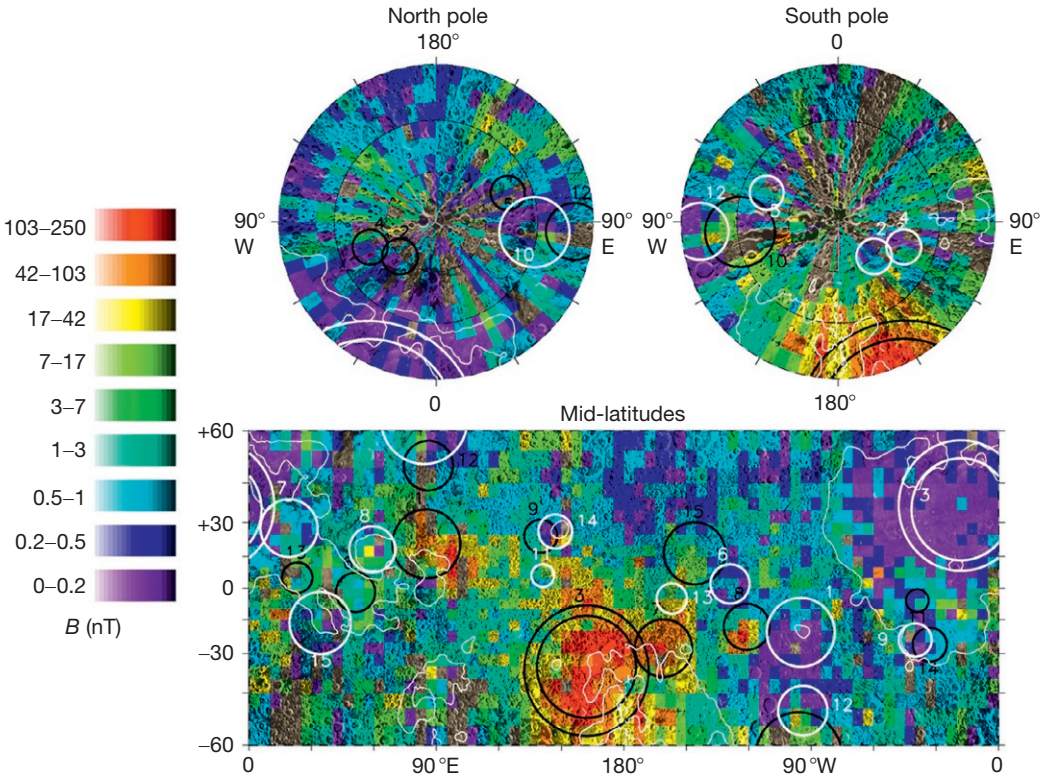

Figure 26 Magnetic field magnitude on the lunar surface as measured by the electron reflection technique. Field magnitudes from 0.2 to 250 nT are represented by colors according to the color bar to the left. The top panel shows the field magnitude in orthographic projections viewed from $+z$ (left) to $-z$ (right); below is a rectangular latitude–longitude projection. The white circles denote major impact basins, and the black circles are drawn at the antipodal site. Reproduced from Mitchell DL, Halekas JS, Lin RP, et al. (2008) Global mapping of lunar crustal magnetic fields by Lunar Prospector. *Icarus* 194: 401–409.

suggests that the lunar dynamo was active only briefly, for perhaps a few hundred million years during the period of time spanned by the (large) impact record. A detailed study of LP magnetometer observations acquired over these same basins at low altitude (~25–40 km) confirms the presence of central features in these Nectarian-aged basins (Hood, 2011). It is worthwhile to note that these features are very weak – just a few tenths of a nanotesla over most of the lunar surface – at satellite altitude. The most intense magnetic anomalies measured directly by the LP magnetometer range from a few to ~25 nT in magnitude (Hood et al., 2001; Richmond and Hood, 2008), sensed at ~15–20 km above the lunar surface. The most extensive magnetic anomalies are mapped antipodal to the Imbrium, Crisium, and Serenitatis basins and over Rimae Sirsalis and the Reiner Gamma formation. The ER observations sense (surface) field magnitudes that are about an order of magnitude greater, but even these estimates may be dramatically biased, that is, underestimated (Halekas et al., 2010), particularly if the anomalies sensed are of smaller spatial scale (<10 km) than sensed by the ~200 eV electrons utilized by the ER technique.

The loose association of lunar magnetic anomalies with impact site antipodes (Lin et al., 1988) has been the most perplexing aspect of lunar magnetization, in part due to the somewhat exotic nature of the proposed mechanism by which an impact on one side of the Moon magnetizes the crust on the opposite side (Hood and Huang, 1991; Hood and Vickery, 1984). Wieczorek et al. (2012) had proposed instead that the global distribution of lunar crustal magnetism is better understood as a consequence of the giant impact event that formed the largest and oldest impact crater on the Moon: that of the South Pole–Aitken basin. They modeled the oblique impact of an ~200 km diameter object and found a distribution of impactor mass emplaced on the lunar surface that resembles the distribution of the most intense lunar magnetic anomalies. They proposed that the magnetized material in the lunar crust was delivered by this differentiated impactor and acquired remanence by cooling in the presence of the Moon's early dynamo field. This proposal neatly circumvents the problem posed by the paltry thermoremanent susceptibility of typical lunar materials, substituting material from the impacting projectile with orders of magnitude greater thermoremanent susceptibility (Wieczorek et al., 2012). It is also consistent with the presence of widely scattered and isolated anomalies of small spatial scale, downrange of the South Pole–Aitken basin and elsewhere.

Complete global maps of the lunar magnetic field were also compiled using direct measurements obtained by the FGM (Purucker, 2008; Purucker and Nicholas, 2010; Richmond and Hood, 2008) at a nominal altitude of ~30 km provided by LP's extended mission. These maps (**Figure 27**) agree well with each other and with the map of field magnitudes derived from ER measurements if one allows for the differences in mapping altitudes. All evidence, to some degree, the broad

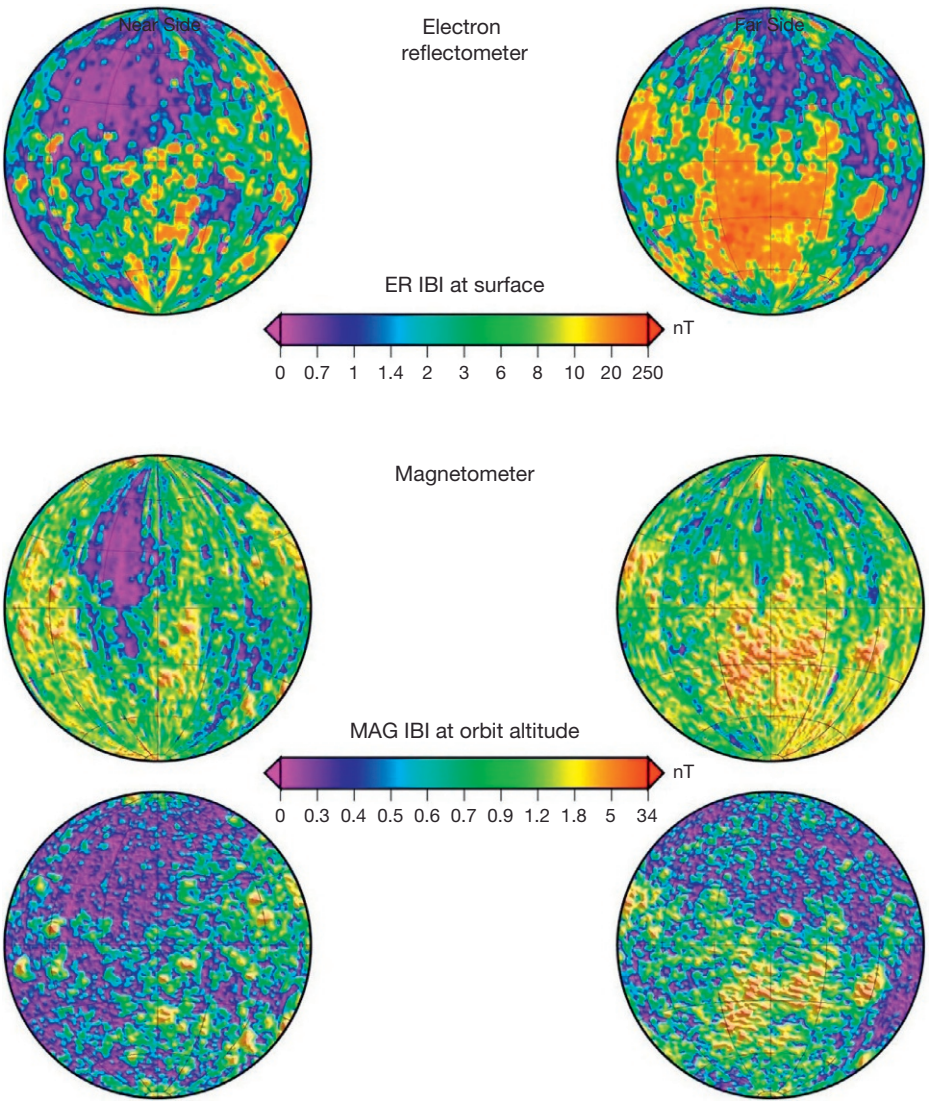

Figure 27 Lambert equal-area projections (nearside: left, farside: right) of the magnitude of the magnetic field above the lunar surface measured by the electron reflectometer (ER) and magnetometer instruments on Lunar Prospector (LP). The ER map (top) shows estimated field magnitudes at the lunar surface, remotely sensed via the electron reflection technique (smoothed over $3^\circ \times 3^\circ$ in latitude and longitude) (Mitchell et al., 2008). The LP magnetometer observations are represented in two forms. The middle set is color-coded to the magnitude of the magnetic field observed at ~30 km altitude after applying a correction for external fields (Richmond and Hood, 2008). The bottom set represents the field magnitude (also at 30 km altitude) derived from a 170° spherical harmonic model fitted to LP magnetometer data (Purucker and Nicholas, 2010). All measurements were acquired by LP at low altitude and primarily on the Moon's nightside, including passages through the Earth's magnetotail, when magnetically quiet conditions were experienced.

weak field associated with Imbrium on the nearside and the relatively strong crustal fields northwest of the South Pole–Aitken basin on the farside. More subtle features associated with other impact basins can also be found, particularly if one uses the ER map (top) as a guide in interpretation of the others. Tsunakawa et al. had applied a regional mapping method to map lunar surface magnetic fields (Tsunakawa et al., 2014), using both LP and SELENE (Kaguya) observations obtained in low lunar orbit (<50 km altitude above the South Pole–Aitken basin). They obtained a rather remarkable correspondence between fields mapped to the lunar surface using the two (independent) data sets, for both weak and strong field regions alike. Weak fields are characterized by surface field magnitudes of a few nanoteslas, whereas the strong field region to the northwest of the South Pole–Aitken basin is characterized by small-scale features with surface fields of ~200 nT. Both regions evidence elongated features, most apparent in the vector components of the mapped field, suggesting lineated source material.

The Moon's crustal magnetism can be understood as a result of impact processes resulting in both SRM and TRM, with rather weak magnetization intensities of a few tenths to a few amperes per meter (Hood, 2011; Purucker and Nicholas, 2010) and with spatial scales at or below the mapping resolution currently available (~5 km). Surface field magnitudes of a few hundred nanoteslas have been detected by the ER method, but Halekas

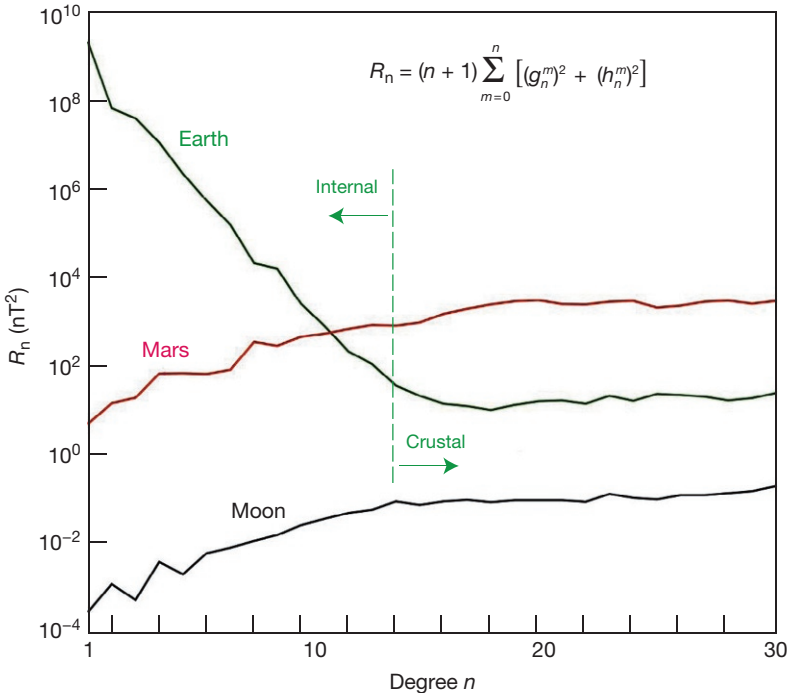

Figure 28 Relative harmonic content (Lowes' spectrum) of the magnetic fields of Earth, Moon, and Mars. The Earth's (internal) field at low degree is produced by the dynamo, but above $n=14$, crustal magnetic fields dominate the spectrum. At all spatial scales, the lunar crust is very weakly magnetized, compared to Earth and (especially) Mars.

et al. (2010) suggested that fields of order 1000 nT might be measured at the surface (with better resolution). One measure of the relative intensity of crustal magnetization is provided by Lowes' spectrum (**Figure 28**), R_n, which is equal to the mean-squared magnetic field amplitude attributed to harmonics of degree n. At all spatial scales measured, and modeled with the aid of spherical harmonics, the lunar crustal magnetic field is about an order of magnitude weaker than that of Earth ($n>14$) and two orders of magnitude weaker than that of Mars. This comparison likely underestimates the great differences in crustal magnetization among these bodies, however. The crustal fields of the Moon and Mars are due to remanent magnetism, whereas the Earth's crustal field is at least partly, if not mostly, induced. The lunar magnetic anomalies appear to be due to discrete magnetic sources scattered in an otherwise nonmagnetic (or very weakly magnetized) crust, whereas the Mars crust must be broadly magnetized throughout but for regions characterized by large impacts or volcanic emplacements.

10.06.6.2 Ganymede

Ganymede, with a radius of 2634 km, is the largest satellite in the solar system. It is slightly larger than the smallest planet in our solar system, Mercury ($R_m=2439$ km), but only about half as massive ($M_g=0.025M_e$). Ganymede may have an Fe or FeS core extending to as much as half the satellite's radius, overlain by a silicate mantle and topped with ~800 km layer of ice (Anderson et al., 1996; Schubert et al., 1996).

The Galileo spacecraft was targeted for several close flybys of Ganymede, the first of which occurred in June of 1996. The first two flyby encounters, with minimum altitudes of 838 and 264 km, demonstrated conclusively the presence of an intrinsic dipolar magnetic field and associated magnetosphere (Gurnett et al., 1996; Kivelson et al., 1996, 1997). Initial analysis of the magnetometer observations revealed a dipole field with equatorial surface field of 750 nT, nearly (within 10°) aligned with the rotation axis. A field of this magnitude is sufficient to produce a Ganymede 'minimagnetosphere' with all of the characteristics normally associated with a trapped particle population. Ganymede's immediate environment (**Figure 29**) includes field lines with both ends anchored within Ganymede, hosting a local trapped radiation environment, 'open' field lines that extend to the Jovian ionosphere, and Jovian field lines. A more comprehensive analysis, performed after the discovery of induced magnetic fields associated with Europa and Callisto (Khurana et al., 1998; Kivelson et al., 1999; Neubauer, 1998; Zimmer et al., 2000), allowed for the presence of an induced field in addition to the main field (Kivelson et al., 2002). This analysis demonstrated that Ganymede has both an inductive response to the time-varying magnetic field, due to currents induced in a hidden global ocean, and an intrinsic field likely due to a dynamo in the deep interior. The intrinsic field is a permanent dipole with a surface equatorial field of 719 nT, tilted by 176° with respect to the rotation axis and rotated 24° toward the trailing hemisphere from the Jupiter-facing meridian plane. The permanent field is perhaps the best evidence that Ganymede has a substantial Fe or FeS core in the interior (Schubert et al., 1996); dynamo action implies that it is fluid, and convecting, with sufficient energy input to sustain the dynamo. Zhan and Schubert (2012) constructed Ganymede dynamo models in which inner core convection is driven by Fe snow and FeS flotation, in addition to

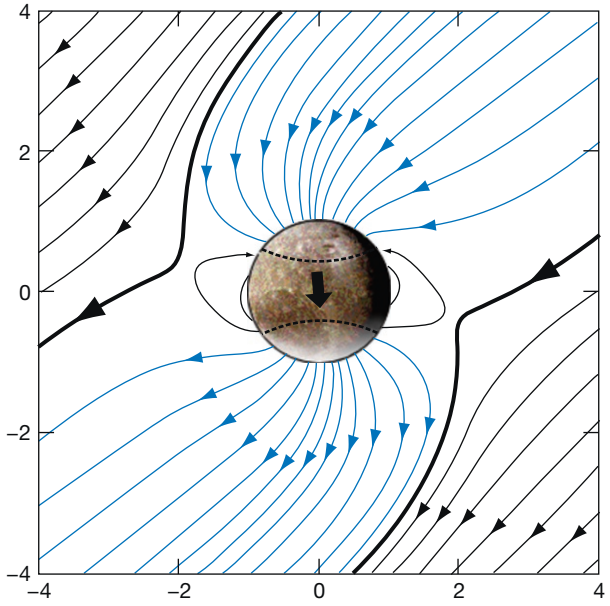

Figure 29 Magnetic field of Ganymede and its immediate environment in meridian plane projection. Ganymede's internal magnetic field moment is indicated with a filled arrow. Low-latitude field lines close within the satellite's interior; high-latitude field lines (blue) form a flux tube with one end rooted in Jupiter's ionosphere; Jovian field lines (black) are separated from those linking Ganymede by a separatrix (heavy black). Adapted from Kivelson MG, Khurana K, and Volwerk M (2002) The permanent and inductive magnetic moments of Ganymede. *Icarus* 157: 507–522.

solid inner core growth. They found that the Fe-snow mechanism is an unlikely candidate for powering Ganymede's dynamo, as it results in a magnetic field that is both weaker and more complex (multipolar) than is observed. Thus, core convection is mainly driven by FeS flotation or inner core growth, both of which concentrate the buoyancy flux near the inner core boundary, where it is most effective (Zhan and Schubert, 2012). However, it is possible (but not likely) that Ganymede's dipolar magnetic field is due to remanent magnetism (Crary and Bagenal, 1998).

10.06.6.3 Io

Io, with a radius of 1821 km, is the most geologically active satellite in the solar system. It is substantially smaller than the smallest magnetic planet in our solar system, Mercury ($R_m = 2439$ km), and less than half as massive as the largest satellite, Ganymede ($M_{io} = 0.39 M_g$). It is quite similar in size and mass to the Moon. Yet it is the most volcanic body in the solar system, evidencing extensive and ongoing volcanic activity owing to tidal heating. Io is a differentiated body with an Fe or FeS core extending to as much as one-third or one-half the satellite's radius, overlain by a silicate mantle and topped with a young, pockmarked crust a few tens of km thick (Anderson et al., 2001).

The Galileo spacecraft executed a number of close flybys of Io, probing fields in Io's immediate vicinity when it was both above and below the magnetodisk current sheet, where it experiences the maximum inducing field. Io, like the icy satellites Europa, Ganymede, and Callisto, evidences an inductive response to the time-varying magnetic field, due to currents flowing in an electrically conductive interior (Khurana et al., 2011). But in contrast to the icy satellites, Io's currents flow in a global subsurface magma layer just beneath the crust, rock heated to ~1200 °C by tidal heating caused by its orbital resonance with Europa and Ganymede (Peale et al., 1979). Khurana et al. (2011) considered the possibility that Io (like Ganymede) sustained a weak dynamo in addition to an inductive response, finding an upper limit of ~100 nT for a surface (equatorial) field, about 20% of the magnitude of the maximum inductive response. They concluded that if Io has a permanent dipole field, it is extremely weak. Why would Io, with a fluid, electrically conductive Fe or FeS core, and prodigious heat flow, not sustain an active dynamo? A likely explanation has to do with where the heat originates. Tidal heating deposits heat just beneath the crust, inhibiting transport of heat from the deep interior (Schubert and Soderlund, 2011; Weinbruch and Spohn, 1995). Convection in the core (and an active dynamo) cannot be maintained absent a temperature differential across the core–mantle boundary.

10.06.7 Discussion

A convenient measure of the complexity of a planetary magnetic field, often used in studies of the magnetic field of the earth and planets, is the 'harmonic spectrum,' sometimes referred to as a 'Lowes' spectrum,' defined as follows (Langel and Estes, 1982; Lowes, 1974):

$$R_n = (n+1)\sum_{m=0}^{n}\left\{\left(g_n^m\right)^2 + \left(h_n^m\right)^2\right\}$$

This quantity is equal to the mean-squared magnetic field intensity over the planet's surface produced by harmonics of degree n. Scaled to the core–mantle boundary with the factor $(a/r_c)^{2n+4}$, this quantity represents the mean-squared magnetic field intensity at the dynamo surface, one of several measures of interest in dynamo theory (e.g., Rädler and Ness, 1990; Schulz and Paulikas, 1990). The Earth's field is well known to high degree and order ($N_{max} = 23$). Scaled to the core–mantle boundary, the spectrum becomes almost flat for $n \leq 14$, suggesting a 'white' spectrum for the dynamo at the core–mantle boundary (e.g., Lowes, 1974). (The Earth's spectrum beyond $n \sim 14$ is attributed to crustal sources.) It is assumed that the core–mantle boundary, the location of which is very accurately known, represents the outer boundary of the geodynamo. Thus, it has often been assumed (prior to knowledge of Uranus' and Neptune's magnetic fields) that a white spectrum at the core–mantle boundary is a common feature of all planetary dynamos (Elphic and Russell, 1978), although in the Earth's case, the quadrupole is considerably less than expected. In **Figure 30**, R_n is calculated using the GSFC 12/83 model for the Earth (Langel and Estes, 1985), the Z_3 model for Saturn (Connerney et al., 1982b), and the Q_3 model for the magnetic field of Uranus (Connerney et al., 1987). For Jupiter, both the O_4 (Acuña and Ness, 1976) and the O_6 models (Connerney, 1992) are shown, illustrating a range of possible values for the quadrupole and octupole. For Uranus, no estimate of the magnitude of

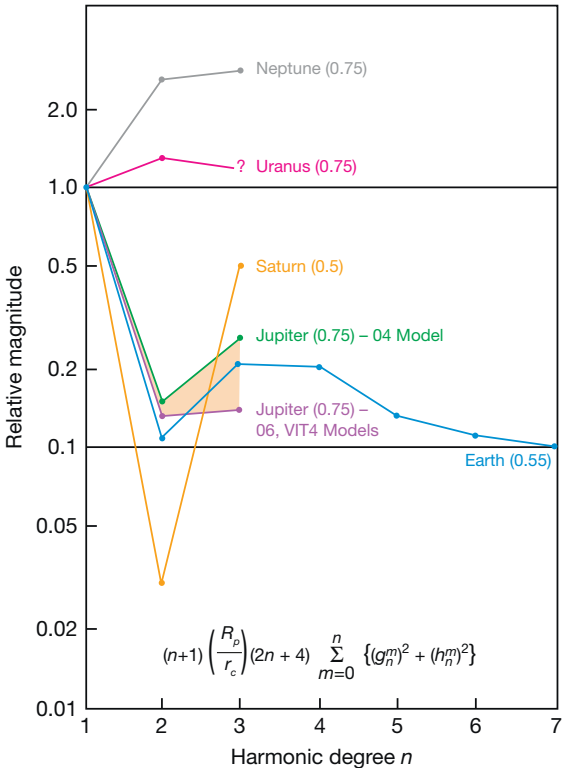

Figure 30 Relative harmonic content (Lowes' spectrum) of spherical harmonic models of Jupiter, Saturn, Uranus, and Neptune, compared with that of Earth, normalized to the assumed core radius (in parentheses) for each planet. Two Jovian magnetic field models are chosen to illustrate the range of possibilities for that planet.

higher-degree ($n>2$) moments can be made, from magnetic measurements alone (but see Holme and Bloxham, 1996 and Herbert, 2009), while for Neptune, terms of higher degree are appreciable, but quite uncertain.

For Jupiter and Saturn, we assume that the dynamo core radius is near the radius of the metallically conducting hydrogen core, $\sim$0.75 and 0.5 planet radius, respectively (e.g., Stevenson, 1983). The transition from molecular hydrogen to the metallic state is likely to be a gradual transition, and for Jupiter, especially, the molecular hydrogen envelope at depth is likely to be electrically conductive and capable of dynamo generation (Hide, 1967; Smoluchowski, 1975; Stanley and Glatzmaier, 2010). So Jupiter's dynamo may extend to $\sim 0.85R_j$ or so. For Uranus and Neptune, we take $r_c = 0.75R_p$ with the expectation that the dynamo for these planets operates in the ice mantle (Hubbard and MacFarlane, 1980; Hubbard and Marley, 1989; Podolak and Reynolds, 1981; Podolak et al., 1991), where ionic conduction prevails (Smoluchowski and Torbett, 1981). The pressure-induced ionization of H_2O provides sufficient electrical conductivity for dynamo generation (Mitchell and Nellis, 1982; Nellis et al., 1988) although it is orders of magnitude less conductive than an iron-rich terrestrial core or a metallically conducting hydrogen core.

In this presentation, the planets fall into two distinct groups, one in which the core surface field is dominated by the dipole (Earth, Jupiter, and Saturn) and one in which the core surface field is dominated by higher-degree contributions (Uranus and Neptune). However, in recognition of the peculiarity of Saturn's axisymmetric field, one might better think in terms of three classifications. In Stevenson's (1982) model, differential rotation of an outer conductive shell attenuates the nonaxisymmetric components of the dynamo within, thereby reducing the observed tilt by an order of magnitude or more from the 'nominal' value. This model has an appealing physical basis (material properties of the H–He fluid) and appears to satisfy other constraints, for example, helium depletion of the gaseous outer envelope and a relatively high planetary heat flux. The dipole-dominated group includes the planets with near alignment of dipole and rotation axes (≤ 10); the other includes the oblique rotators Uranus (59°) and Neptune (47°), the planets with a very large angular separation of the dipole and rotation axes. **Table 8** provides a comparison of the gross characteristics of the magnetic fields of the planets and satellites with active dynamos, using the eccentric dipole representation (Connerney, 1993). The eccentric dipole is computed from a spherical harmonic model and provides a useful characterization of the field at a distance, the dipole magnitude, tilt, and offset. Estimated minimum and maximum surface fields are computed using spherical harmonic representations, taking into account dynamical flattening, which is most significant for the gas giants.

10.06.8 Summary

The magnetic planets (and satellites) of the solar system provide a rich diversity of objects of relevance to dynamo theory. Mercury, Mars, Earth, and Ganymede have substantial iron cores with varying amounts of S or some other alloying elements; each has, or once had, an active dynamo. In this group, Mars and Earth appear similar, although the Mars dynamo is no longer active, and we have only the crustal remanence that remains today as evidence of its dynamo. Mercury and Ganymede are similar in size as well as magnetic properties; both have diminutive dynamos often considered so weak that alternatives to an active dynamo are proposed (Aharonson et al., 2004; Crary and Bagenal, 1998; Giampieri and Balogh, 2002). Mercury's weak field has been attributed to a dynamo operating beneath a stably stratified and electrically conductive shell (Christensen, 2006) that serves to attenuate the field or, alternately, a thin shell dynamo operating above a solid and electrically conductive inner core (Stanley et al., 2005). Both Mercury and Ganymede have dipolar or nearly dipolar fields more or less aligned with the spin axis.

Unmagnetized Venus reminds us that in dynamo theory, the 'devil is in the details.'

In Jupiter and Saturn, we have two planets of nearly the same composition and comparable size but with magnetic fields that are worlds apart. Jupiter's dynamo produces a magnetic field resembling Earth's, while Saturn's is uniquely spin-axisymmetric. Stevenson's account of Saturn's internal structure and magnetic field is appealing, as it provides a vehicle for understanding the differences between these gas giant planets. In Uranus and Neptune, we have again two planets of similar composition and size, this time with similar magnetic fields (fortunately!). These icy twins form a category of 'oblique rotators' with large dipole tilts and eccentric magnetic fields.

Table 8 Summary of planetary and satellite magnetic fields

	Mercury	*Earth*	*Jupiter*	*Saturn*	*Uranus*	*Neptune*	*Ganymede*
M (Gauss)	0.002	0.306	4.30	0.215	0.228	0.142	0.007
θ_d (°)	0.0	11.2	9.4	0.0	58.6	46.9	0.0
ϕ_d (°)	n/a	70.8	200.1	n/a	53.6	72.0	n/a
$\|r\|$ (R_p)	0.17	0.076	0.119	0.038	0.352	0.485	–
$\|B_s\|$ (Gauss) Min–max	0.0025–0.007	0.24–0.66	4.0–13.0	0.18–0.84	∼0.1–1.0	∼0.1–0.9	0.007–0.015
Oblateness	n/a	1/298	1/15.4	1/10.6	1/41.6	1/47.6	n/a
Model	(1)	GSFC1283	O_6	Z_3	Q_3	O_8	(2)

Dipole parameters are obtained from spherical harmonic models using the eccentric dipole representation (Connerney, 1993) unless otherwise noted; this is a good approximation for distant fields. The offset of the eccentric dipole ($|r|$) is given in units of the planet radius. The minimum and maximum magnetic field magnitude on the planet's surface ($|B_s|$) is obtained using the spherical harmonic model and oblateness noted. (1) Mercury model from Alexeev et al. (2010) and (2) Ganymede model from Kivelson et al. (2012).

Dynamo generation within these planets takes place in the relatively poorly conducting 'ice' mantle that sits atop a stably stratified and electrically conductive 'superionic' water interior (Redmer et al., 2011). Dynamos operating in spherical shells can produce dipole fields with large dipole tilts (Aubert and Wicht, 2004) and the harmonic content characteristic of ice giant dynamos (Stanley and Bloxham, 2006), but none thus far mimic the hemispheric asymmetry observed of such planetary fields. Heuristically, it is tempting to associate dipole dominance with small dipole tilt and dipole deficiency with large dipole tilt; it appears that dynamos operating in less conductive fluids are in the latter group. If dynamos operate with roughly comparable magnetic Reynolds numbers and convective velocities, those operating in poorly conductive fluids will require relatively large spatial scale lengths (Connerney, 1993; Connerney et al., 1987). If so, an ice giant dynamo, characterized by a relatively small number of large convective cells, might be expected to have a large dipole tilt (e.g., Elsasser, 1946; Parker, 1969).

In little more than three decades, we have sampled the magnetic fields of every planet in the solar system, some several times over. This diverse sample set challenges our understanding of the generation of magnetic fields in planetary interiors. Dynamos are ubiquitous and evidently remarkably responsive to subtle differences in interior composition, heat flow, and convection and as such offer clues to a planet's interior structure and evolution. For the present, dynamo theory matures on the heels of such discoveries (Schubert and Soderlund, 2011; Stanley and Glatzmaier, 2010); for the near future, we may all look forward to the global mapping of Jupiter's magnetic field in the coming years and that of Saturn, Mercury, and Ganymede as well. Remote Uranus and Neptune may hold onto their secrets a bit longer.

10.07.1 Historical Introduction

While the Earth's magnetism has been studied for centuries starting with the first scientific monograph of Gilbert (1600), the question of the magnetism of other planets had received scant attention until recently because of the lack of relevant observations. Only in 1955, clear evidence for the existence of a planetary magnetic field other than the geomagnetic one was obtained through the observation of the Jovian decametric radio waves (Burke and Franklin, 1955). Since it had been more or less accepted until the end of the nineteenth century that geomagnetism arises from the remnant magnetization of the Earth, similar properties may have been assumed for the other terrestrial planets and the Moon. This view lost its appeal, however, when it became evident that the Curie temperature is exceeded in the Earth below a depth of about 30 km. Ferromagnetic materials in the Earth's crust could thus explain only magnetic fields with a relatively short wavelength.

The current period of intense research on the magnetism of planets other than that of the Earth started with the first detailed measurement of Jupiter's magnetic field by the Pioneer 10 space probe in 1973 and the discovery of Mercury's magnetism by Mariner 10 in 1974. In the early 1970s, also the development of the theory of magnetohydrodynamic (MHD) dynamos had started in which the reaction of the Lorentz force of the generated magnetic field is taken into account in physically realistic configurations (Childress and Soward, 1972). Until that time, dynamo theoreticians had focused their attention on the kinematic problem in which the possibility of growing magnetic fields driven by somewhat arbitrarily chosen velocity fields is considered. It must be remembered that only a few years earlier, it had been demonstrated in a mathematically convincing way by Backus (1958) and Herzenberg (1958) that the homogeneous dynamo process of the generation of magnetic fields in a singly connected domain of an electrically conducting fluid is indeed possible. Doubts about the feasibility of this process that had first been proposed by Larmor (1919) had persisted after Cowling (1934) had proved that purely axisymmetric fields could not be generated in this way.

The complexity of the MHD dynamo problem described by the nonlinearly coupled Navier–Stokes equations and the equation of magnetic induction had prevented progress in understanding planetary dynamos through analytic solutions. Only the advent of powerful enough computers in the 1990s has allowed to solve numerically the coupled three-dimensional partial differential equations through forward integration in time. Even today and for the foreseeable future, the limits of computer capacity will permit the exploration of only a small fraction of the parameter space of interest for the understanding of planetary dynamos (see also **Chapters 8.03** and **8.10**).

In view of the difficulties of a rigorous theory of planetary dynamos, many attempts have been made to obtain simple similarity relationships that would fit the observed planetary magnetic moments as function of certain properties of the planets. Some early proponents have gone as far as claiming the existence of a 'magnetic Bode's law' corresponding to a relationship between the magnetic moment and size or angular momentum of a planet in analogy to the Titius–Bode law for the radii of planetary orbits. Just as in the latter case, however, attempts to derive a magnetic Bode's law from basic physical principles have failed.

Other proposals have taken into account physical forces. Since a common ingredient of planetary dynamos is the existence of a fluid part of the core with a sufficiently high electrical conductivity, the latter parameter together with the core radius and the angular velocity of the planetary rotation usually enters

 http://dx.doi.org/10.1016/B978-0-444-53802-4.00172-X

the similarity relationships such as those proposed by Hide (1974), Busse (1976), Jacobs (1979), and Dolginov (1977). Malkus (1968, 1994) had argued for the precession of the Earth as the cause of geomagnetism, and he and Vanyo (1984) had demonstrated through laboratory experiments that precession and tides may cause turbulent motions in fluid planetary cores. Dolginov (1977) proposed a scaling law for the precessional origin of all planetary magnetic fields. While a dynamo driven by turbulent flows caused by precession and tides cannot be easily excluded in the case of the Earth (Tilgner, 2007), it is much less likely in the case of other planets such as Uranus for which precessional torques are rather minute. Just as a common precessional origin of planetary magnetism is not regarded as feasible, so have all other proposed similarity relationships lost in appeal and are no longer seriously considered. We shall return, however, to scaling relationships based more directly on the basic MHD equations in Section 10.07.5.

10.07.2 General Remarks on the Dynamo Theory of Planetary Magnetism

Since the proposal of the geodynamo as the cause of the Earth's magnetism had been in doubt for a long time before 1958, numerous alternative proposals had been made in the literature. Among these, only the possibility that thermoelectric currents may generate a planetary magnetic field is still discussed in the case of Mercury (Giampieri and Balogh, 2002; Stevenson, 1987). For a discussion of the failings of the various proposals for nondynamo origins of planetary magnetic fields, we refer to the papers of Bullard (1949) and Stevenson (1983).

Dynamos generally convert mechanical energy into magnetic one. In contrast to the technical dynamo that is characterized by a multiply connected region of high electrical conductivity, that is, it depends on an appropriate wiring, planetary dynamos are referred to as homogeneous dynamos since they operate in a singly connected fluid domain of high electrical conductivity. Since flows in planetary cores with active dynamos are usually turbulent, the small-scale structure of the magnetic field is correspondingly chaotic. The large-scale structure, however, can be quite regular. One distinguishes 'steady' and oscillatory dynamos. The most famous example of the latter kind is the solar dynamo that exhibits a well-defined period of about 22 years. The geodynamo, on the other hand, is usually regarded as a 'steady' dynamo, even though it varies in its amplitude by a factor of two or more on the magnetic diffusion timescale and reverses its polarity on a longer timescale. For an alternative view, see Busse and Simitev (2008). A measure of the magnetic diffusion time is given by the decay time, $t_d = \sigma\mu r_0^2/\pi^2$, of the magnetic field in the absence of fluid motions. Here, σ and μ refer to the electrical conductivity and the magnetic permeability of the planetary core of radius r_0. In the case of the Earth, the decay time is of the order of 20 000 years, but it may vary between a few hundred and a million years for other examples of planetary dynamos.

The theory of homogeneous dynamos is based on Maxwell's equations for the magnetic flux density $\boldsymbol{B}$, the electric current density $\boldsymbol{j}$, and the electric field $\boldsymbol{E}$ in the MHD approximation in which the displacement current is neglected. This approximation is highly accurate as long as the fluid velocity is small compared with the velocity of light, which is certainly the case for all planetary applications. These equations together with Ohm's law for a moving conductor are given by

$$\nabla\cdot\boldsymbol{B}=0,\quad \frac{\partial}{\partial t}\boldsymbol{B}=-\nabla\times\boldsymbol{E} \qquad [1a]$$

$$\nabla\times\boldsymbol{B}=\mu\boldsymbol{j},\quad \boldsymbol{j}=\sigma(\boldsymbol{v}\times\boldsymbol{B}+\boldsymbol{E}) \qquad [1b]$$

where μ is the magnetic permeability of the fluid and σ is its electrical conductivity. These 'pre-Maxwell' equations have the property that they are invariant with respect to a Galilei transformation, that is, the equations remain unchanged in a new frame of reference moving with the constant velocity vector $\boldsymbol{V}$ relative to the original frame of reference. Indicating the variables of the new frame by a prime, we find

$$\boldsymbol{v}'=\boldsymbol{v}-\boldsymbol{V},\quad \frac{\partial}{\partial t'}=\frac{\partial}{\partial t}+\boldsymbol{V}\cdot\nabla \qquad [2a]$$

$$\boldsymbol{B}'=\boldsymbol{B},\quad \boldsymbol{E}'=\boldsymbol{E}+\boldsymbol{V}\times\boldsymbol{B},\quad \boldsymbol{j}'=\boldsymbol{j} \qquad [2b]$$

This invariance is the basis for the combination in MHD of eqns [1a] and [1b] with the equations of hydrodynamics in their usual nonrelativistic form. It is remarkable that this invariance does hold not only with respect to a Galilei transformation but also with respect to a transformation to a rotating frame of reference. In that case, $\boldsymbol{V}$ is replaced by $\boldsymbol{\Omega}\times\boldsymbol{r}$ in eqns [2a] and [2b], but when $\frac{\partial}{\partial t'}$ is operating on any vector $\boldsymbol{a}$, the term $-\boldsymbol{\Omega}\times\boldsymbol{a}$ must be added on the right-hand side, since even a constant vector field becomes time-dependent when seen from a rotating frame unless it is parallel to $\boldsymbol{\Omega}$.

Elimination of $\boldsymbol{E}$ and $\boldsymbol{j}$ from eqns [1a] and [1b] yields the equation of magnetic induction:

$$\nabla\times\left(\frac{1}{\sigma\mu}\nabla\times\boldsymbol{B}\right)=\frac{\partial}{\partial t}\boldsymbol{B}+\nabla\times(\boldsymbol{v}\times\boldsymbol{B}) \qquad [3]$$

which for a solenoidal velocity field υ and a constant magnetic diffusivity $\lambda=(\sigma\mu)^{-1}$ can be further simplified:

$$\left(\frac{\partial}{\partial t}+\boldsymbol{v}\cdot\nabla\right)\boldsymbol{B}-\lambda\nabla^2\boldsymbol{B}=\boldsymbol{B}\cdot\nabla\boldsymbol{v} \qquad [4]$$

This equation has the form of a heat equation with the magnetic field line stretching term on the right-hand side acting as a heat source. This interpretation is especially useful for the dynamo problem. In order that a magnetic field $\boldsymbol{B}$ may grow, the term on the right-hand side of eqn [4] must overcome the effect of the magnetic diffusion term on the left-hand side. Using a typical velocity U and a typical length scale d, the ratio of the two terms can be estimated by the magnetic Reynolds number Rm:

$$Ud/\lambda\equiv Rm \qquad [5]$$

Only when Rm is of the order one or larger may growing magnetic fields become possible.

In the following, we shall first consider the mathematical formulation of the problem of convection-driven dynamos in rotating spherical shells in a simple form in which only the physically most relevant parameters are taken into account. Before discussing dynamo solutions in Section 10.07.5, we shall briefly outline in Section 10.07.4 properties of convection

in the absence of a magnetic field. Applications to various planets and moons will be considered in Section 10.07.6 of this article, and some concluding remarks are given in Section 10.07.7.

10.07.3 Mathematical Formulation of the Problem of Spherical Dynamos

A sketch of the geometric configuration that will be considered is shown in Figure 1. For the equations describing convection-driven dynamos in the frame rotating with the angular velocity Ω, we use a standard formulation that has also been used for a dynamo benchmark (Christensen et al., 2001). But we use a different scaling and assume that a more general static state exists with the temperature distribution $T_S = T_0 - \beta d^2 r^2/2 + \Delta T \eta r^{-1}(1-\eta)^{-2}$ where η denotes the ratio of inner to outer radius of the spherical shell, d is its thickness, and rd is the distance from the center. ΔT is the temperature difference between the boundaries in the special case $\beta = 0$. In the case $\Delta T = 0$, the static temperature distribution T_S corresponds to that of a homogeneously heated sphere with the heat source density proportional to the parameter β. The gravity field is given by $g = -\gamma d\boldsymbol{r}$ where $\boldsymbol{r}$ is the dimensionless position vector with respect to the center of the sphere.

In addition to d, the time d^2/ν, the temperature $\nu^2/\boldsymbol{\gamma\alpha}\mathrm{d}^4$, and the magnetic flux density $\nu(\mu\varrho)^{1/2}/d$ are used as scales for the dimensionless description of the problem where ν denotes the kinematic viscosity of the fluid, κ its thermal diffusivity, and ϱ its density. The Boussinesq approximation is used in that ϱ is assumed to be constant except in the gravity term where its temperature dependence given by the constant $\alpha \equiv -(\mathrm{d}\varrho/\mathrm{d}T)/\varrho$ is taken into account. The dimensionless equations of motion, the heat equation for the deviation Θ of the temperature field from the static distribution, and the equation of magnetic induction thus assume the form

$$\nabla^2\boldsymbol{v} + \boldsymbol{B}\cdot\nabla\boldsymbol{B} + \boldsymbol{r}\Theta - \nabla\pi = P^{-1}(\partial_t\boldsymbol{v} + \boldsymbol{v}\cdot\nabla\boldsymbol{v}) + \tau\mathbf{k}\times\boldsymbol{v} \qquad [6a]$$

$$\nabla\cdot\boldsymbol{v} = 0 \qquad [6b]$$

$$\nabla^2\Theta + \left[R_\mathrm{i} + R_e\eta r^{-3}(1-\eta)^{-2}\right]\boldsymbol{r}\cdot\boldsymbol{v} = P(\partial_\mathrm{t} + \boldsymbol{v}\cdot\nabla)\Theta \qquad [6c)]$$

$$P_\mathrm{m}\left(\frac{\partial}{\partial t} + \boldsymbol{v}\cdot\nabla\right)\boldsymbol{B} - \nabla^2\boldsymbol{B} = P_\mathrm{m}\boldsymbol{B}\cdot\nabla\boldsymbol{v} \qquad [6d]$$

where $\mathbf{k}$ is the unit vector in the direction of the axis of rotation and where $\nabla\pi$ includes all terms that can be written as gradients. The Rayleigh numbers R_i and R_e, the Coriolis parameter τ, the Prandtl number P, and the magnetic Prandtl number P_m are defined by

$$R_\mathrm{i} = \frac{\alpha\gamma\beta d^6}{\nu\kappa}, \quad R_\mathrm{e} = \frac{\alpha\gamma\Delta T d^4}{\nu\kappa} \qquad [7a]$$

$$\tau = \frac{2\Omega d^2}{\nu}, \quad P = \frac{\nu}{\kappa}, \quad P_\mathrm{m} = \frac{\nu}{\lambda} \qquad [7b]$$

For simplicity, $R_e = 0$ will be assumed unless indicated otherwise. The notation $R \equiv R_i$ will thus be used in the following.

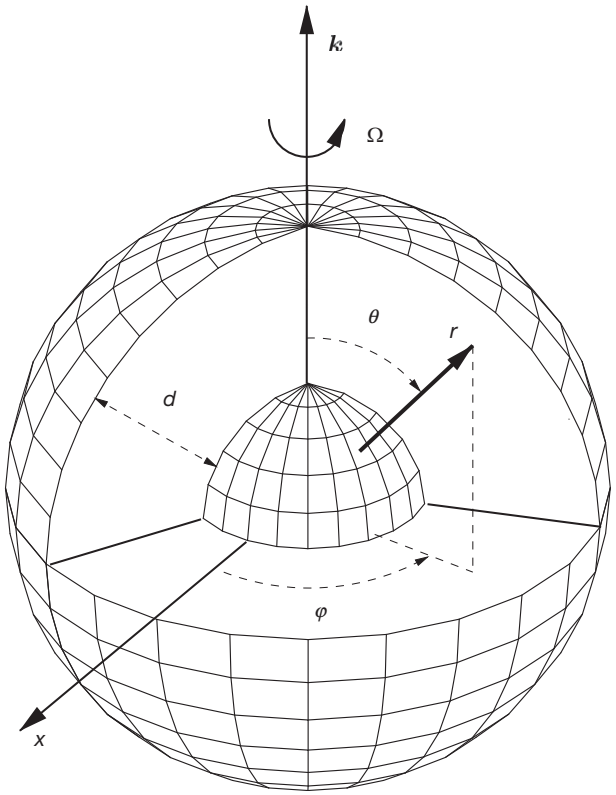

Figure 1 Geometric configuration of the problem. A part of the outer spherical surface is removed to expose the interior of the shell to which the conducting fluid is confined.

Instead of the Coriolis parameter τ, often its inverse, the Ekman number $E \equiv 2/\tau$, is used. The Prandtl number P has been added as an important parameter of the problem even though $P = 1$ is often assumed with the argument that all effective diffusivities are equal in turbulent media. The effective diffusivities of scalar and vector quantities in turbulent fluid flow differ in general, however, and large differences in the corresponding molecular diffusivities will not be erased entirely in the turbulent case.

Since the velocity field $\boldsymbol{v}$ and the magnetic flux density $\boldsymbol{B}$ are solenoidal vector fields, the general representation in terms of poloidal and toroidal components can be used:

$$\boldsymbol{v} = \nabla \times (\nabla \Phi \times \boldsymbol{r}) + \nabla \Psi \times \boldsymbol{r} \qquad [8a]$$

$$\boldsymbol{B} = \nabla \times (\nabla h \times \boldsymbol{r}) + \nabla g \times \boldsymbol{r} \qquad [8b]$$

By multiplying the $(\text{curl})^2$ and the curl of eqn [6a] by $\boldsymbol{r}$, we obtain two equations for Φ and Ψ:

$$\left[\left(\nabla^2 - \partial_t\right) L_2 + \tau \partial_\phi\right] \nabla^2 \Phi + \tau Q \Psi - L_2 \Theta$$

$$= -\boldsymbol{r} \cdot \nabla \times [\nabla \times (\boldsymbol{v} \cdot \nabla \boldsymbol{v} - \boldsymbol{B} \cdot \nabla \boldsymbol{B})] \qquad [9a]$$

$$\left[\left(\nabla^2 - \partial_t\right) L_2 + \tau \partial_\phi\right] \Psi - \tau Q \Phi = \boldsymbol{r} \cdot \nabla \times (\boldsymbol{v} \cdot \nabla \boldsymbol{v} - \boldsymbol{B} \cdot \nabla \boldsymbol{B}) \qquad [9b]$$

where ∂_t and ∂_ϕ denote the partial derivatives with respect to time t and with respect to the angle ϕ of a spherical system of coordinates r, θ, ϕ and where the operators L_2 and Q are defined by

$$L_2 \equiv -r^2 \nabla^2 + \partial_r (r^2 \partial_r)$$

$$Q \equiv r \cos\theta \nabla^2 - (L_2 + r\partial_r)(\cos\theta \partial_r - r^{-1} \sin\theta \partial_\theta)$$

The equations for h and g are obtained by multiplication of eqn [6d] and of its curl by $\boldsymbol{r}$:

$$\nabla^2 L_2 h = P_\mathrm{m} [\partial_t L_2 h - \boldsymbol{r} \cdot \nabla \times (\boldsymbol{v} \times \boldsymbol{B})] \qquad [10a]$$

$$\nabla^2 L_2 g = P_\mathrm{m} [\partial_t L_2 g - \boldsymbol{r} \cdot \nabla \times (\nabla \times (\boldsymbol{v} \times \boldsymbol{B}))] \qquad [10b]$$

Either rigid boundaries with fixed temperatures as in the benchmark case (Christensen et al., 2001),

$$\Phi = \partial_r (r\Phi) = \Psi = \Theta = 0 \quad \text{at } r = r_i \equiv \eta/(1-\eta) \quad \text{and at } r$$

$$= r_\mathrm{o} \equiv (1-\eta)^{-1} \qquad [11]$$

or stress-free boundaries with fixed temperatures,

$$\Phi = \partial_{rr}^2 \Phi = \partial_r (\Psi/r) = \Theta = 0 \quad \text{at } r = r_i$$

$$\equiv \eta/(1-\eta) \quad \text{and at } r = r_o = (1-\eta)^{-1} \qquad [12]$$

are often used. The latter boundary conditions are assumed in the following since they allow to cover numerically a larger region of the parameter space. The case $\eta = 0.4$ will be considered unless indicated otherwise. It provides a good compromise for the study of both the regions inside and outside the tangent cylinder. The latter is the cylindrical surface touching the inner spherical boundary at its equator. For the magnetic field, electrically insulating boundaries are used such that the poloidal function h must be matched to the function $h^{(e)}$ that describes the potential fields outside the fluid shell:

$$g = h - h^{(e)} = \partial_r \left(h - h^{(e)}\right) = 0 \quad \text{at } r = r_i \quad \text{and } r = r_o \qquad [13]$$

Computations for the case of an inner boundary with no-slip conditions and an electrical conductivity equal to that of the fluid have also been done. The numerical integration of eqns [2a] and [2b] together with boundary conditions [4] proceeds with the pseudospectral method as described by Tilgner and Busse (1997) and Tilgner (1999), which is based on an expansion of all dependent variables in spherical harmonics for the θ, ϕ dependences, that is,

$$\Phi = \sum_{l,m} V_l^m(r,t) P_l^m(\cos\theta) \exp\{im\phi\} \qquad [14]$$

and analogous expressions for the other variables, Ψ, Θ, h, and g. P_l^m denotes the associated Legendre functions. For the r-dependence, expansions in Chebyshev polynomials are used.

For the computations to be reported in the following, a minimum of 33 collocation points in the radial direction and spherical harmonics up to the order 64 have been used. But in many cases, the resolution was increased to 49 collocation points and spherical harmonics up to the order 96 or 128.

It should be emphasized that the static state $\boldsymbol{v} = \boldsymbol{B} = \Theta = 0$ represents a solution of eqns [6a]–[6d] for all values of the Rayleigh numbers R_i and R_e, but this solution is unstable except for low or negative values of the latter parameters. Similarly, there exist solutions with $\boldsymbol{B} = 0$, but $\boldsymbol{v} \neq 0$, $\Theta \neq 0$, for sufficiently large values of either R_i or R_e or both, but, again, these solutions are unstable for sufficiently large values of P_m with respect to disturbances with $\boldsymbol{B} \neq 0$. Dynamo solutions as all solutions with $\boldsymbol{B} \neq 0$ are called, are thus removed by at least two bifurcations from the basic static solution of the problem.

Finally, we present in **Table 1** a list of the most important parameters used in the following sections.

10.07.4 Convection in Rotating Spherical Shells

For an introduction to the problem of convection in spherical shells, we refer to the review of Busse (2002a). Convection tends to set in first outside the tangent cylinder in the form of thermal Rossby waves for which the Coriolis force is balanced almost entirely by the pressure gradient. The model of the rotating cylindrical annulus has been especially useful for

Table 1 Important dimensionless parameters

E	Average density of kinetic energy	[18a] and [18b]
E_p, E_t	Energy densities of poloidal and toroidal components of motion	[18a] and [18b]
η	Radius ratio of spherical fluid shell	
Λ	Elsasser number	[19]
M	Average magnetic energy density	[19]
M_p, M_t	Energy densities of poloidal and toroidal components of the magnetic field	[19]
Nu	Nusselt number	[16]
P	Prandtl number	[7b]
P_m	Magnetic Prandtl number	[7b]
R	Rayleigh number	[7a]
R_c	Critical value of R for the onset of convection	
Rm	Magnetic Reynolds number $= P_\mathrm{m}\sqrt{2E}$	
τ	Coriolis parameter	[7b]

the understanding of this type of convection. A rough idea of the dependence of the critical Rayleigh number R_c for the onset of convection on the parameters of the problem can be gained from the expressions derived from the annulus model (Busse, 1970):

$$R_c = 3\left(\frac{P\tau}{1+P}\right)^{\frac{4}{3}}(\tan\theta_m)^{\frac{8}{3}} r_m^{-\frac{1}{3}} 2^{-\frac{2}{3}} \qquad [15a]$$

$$m_c = \left(\frac{P\tau}{1+P}\right)^{\frac{1}{3}}(r_m\tan\theta_m)^{\frac{2}{3}} 2^{-\frac{1}{6}} \qquad [15b]$$

$$\omega_c = \left(\frac{\tau^2}{(1+P)^2 P}\right)^{\frac{1}{3}} 2^{-\frac{5}{6}}(\tan^2\theta_m/r_m)^{\frac{2}{3}} \qquad [15c]$$

where r_m refers to the mean radius of the fluid shell, $r_m=(r_i+r_o)/2$, and θ_m refers to the corresponding colatitude, $\theta_m=\arcsin(r_m(1-\eta))$. The azimuthal wavenumber of the preferred mode is denoted by m_c, and the corresponding angular velocity of the drift of the convection columns in the prograde direction is given by ω_c/m_c.

In Figure 2, expressions [15a] and [15c] are compared with accurate numerical values that indicate that the general trend is well represented by expressions [15a] and [15c]. The same property holds for m_c. For a rigorous asymptotic analysis in the case $P=1$ including the radial dependence, we refer to Jones et al. (2000).

It is evident from Figure 2 that the agreement between expressions [15a]–[15c] and the numerical values deteriorates as low values of P are approached. This behavior is caused by the fact that instead of the thermal Rossby wave mode, the inertial mode of convection becomes preferred at onset for sufficiently low Prandtl numbers. It is characterized by convection cells attached to the equatorial region of the outer boundary not unlike the 'banana cells' seen in the narrow gap experiment of Figure 3. The equatorially attached convection does indeed represent an inertial wave modified by the effects of viscous dissipation and thermal buoyancy. An analytic description of this type of convection can thus be attained through the introduction of viscous friction and buoyancy as perturbations, as has been done by Zhang (1994) and Busse and Simitev (2004) for stress-free boundaries and by Zhang (1995) for no-slip boundaries. According to Ardes et al. (1997), equatorially attached convection is preferred at onset for $\tau<\tau_1$ where τ_1 increases in proportion to $P^{-1/2}$.

A third form of convection is realized in the polar regions of the shell that comprise the two fluid domains inside the tangent cylinder. Since gravity and rotation vectors are nearly parallel in these regions (unless values of η close to unity are used), convection resembles the kind realized in a horizontal layer heated from below and rotating about a vertical axis. Because the Coriolis force cannot be balanced by the pressure gradient in this case, the onset of convection is delayed to higher values of R where convection outside the tangent cylinder has reached already high amplitudes. In the case of $\eta=0.4$, the onset of convection in the polar regions typically occurs at the Rayleigh numbers that exceed the critical values R_c for the onset of convection outside the tangent cylinder by a factor of the order 4. Except for the case of very low Prandtl numbers, the retrograde differential rotation in the polar regions generated by convection outside the tangent cylinder tends to facilitate polar convection by reducing the rotational constraint. A tendency towards an alignment of convection rolls with the north–south direction (Busse and Cuong, 1977) can be noticed, but this property is superseded by the instabilities of the Küppers–Lortz type (for an experimental demonstration, see Busse and Heikes, 1980) and by interactions with turbulent convection outside the tangent cylinder.

Typical features of low and high Prandtl number convection are illustrated in Figure 4. The columnar nature of

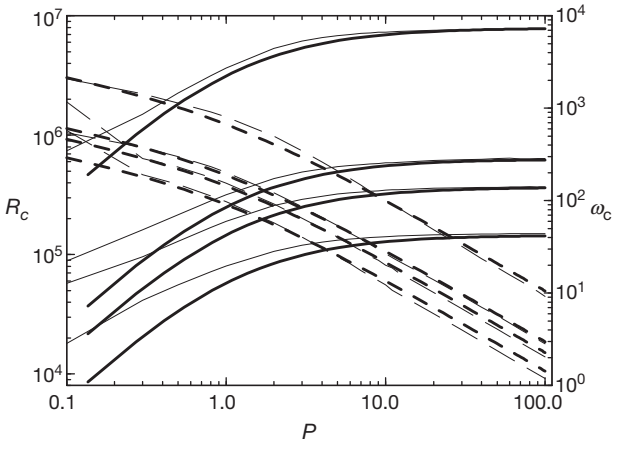

Figure 2 Critical Rayleigh number R_c (thin solid lines) and frequency ω_c (right ordinate, thin dashed lines) as a function of the Prandtl number P in the case $\eta=0.4$ for the Coriolis numbers $\tau=5\times10^3$, 10^4, 1.5×10^4, and 10^5 (from bottom to top). The thick lines correspond to expressions [15a] and [15c].

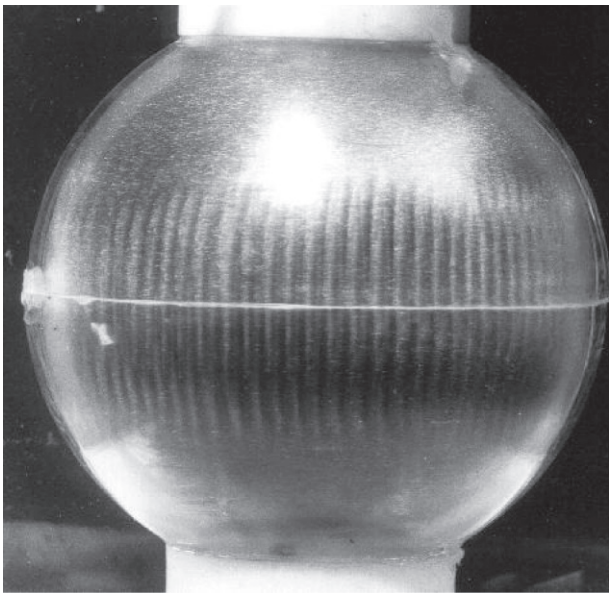

Figure 3 Banana cells in a thin rotating spherical fluid shell cooled from within. Convection driven by centrifugal buoyancy is made visible by a suspension of tiny flakes that become aligned with the shear. Reproduced from Busse FH and Carrigan CR (1976) Laboratory simulation of thermal convection in rotating planets and stars. *Science* 191: 81–83.

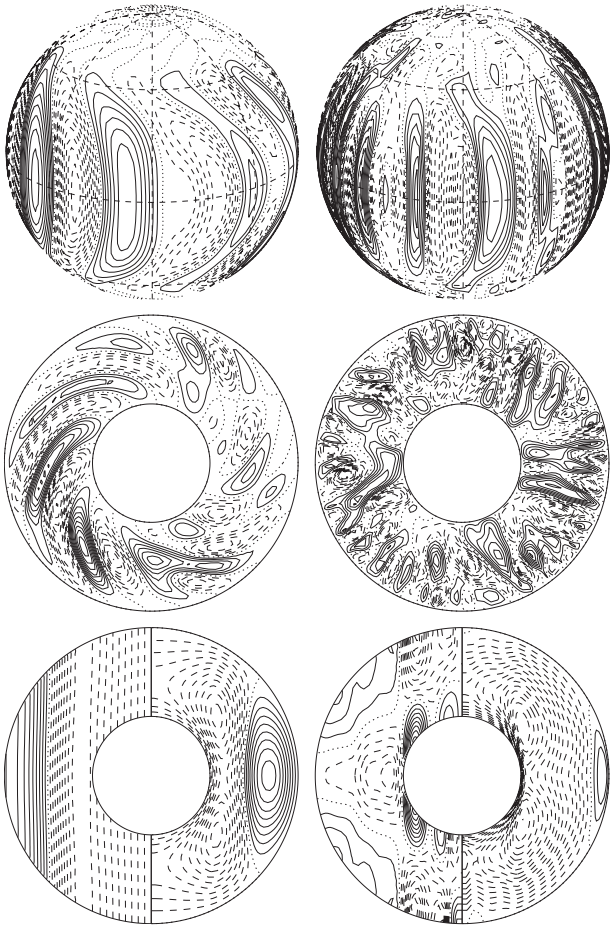

Figure 4 Convection in rotating spherical fluid shells in the cases $\tau = 10^4$, $R = 4 \times 10^5$, and $P = 1$ (left column) and $\tau = 5 \times 10^3$, $R = 8 \times 10^5$, and $P = 20$ (right column). Lines of constant u_r in the middle spherical surface, $r = r_i + 0.5$, are shown in the upper row. The plots of the middle row show streamlines, $r\partial\Phi/\partial\varphi = \text{const.}$, in the equatorial plane. The lowermost plots indicate lines of constant mean azimuthal velocity $\overline{u}_\varphi$ in the left halves and isotherms of $\overline{\Theta}$ in the right halves.

convection does not vary much with P, as is evident from the top two plots of the figure. At Prandtl numbers of the order unity or less, but not in the case of inertial convection, the convection columns tend to spiral away from the axis and thereby create a Reynolds stress that drives a strong geostrophic differential rotation, as shown in the bottom left plot of the figure. This differential rotation in turn promotes the tilt and a feedback loop is thus created. The generation of differential rotation by convection in rotating spherical shells was first demonstrated by Busse (1970). In this paper, a simple analytic model is described (see also Busse, 2002a). At high values of P, the Reynolds stress becomes negligible, and no significant tilt of the convection columns is apparent. In this case, the differential rotation is generated in the form of a thermal wind caused by the latitudinal gradient of the axisymmetric component of Θ.

Among the properties of convection at finite amplitudes, the heat transport is the most important one. Customarily, its efficiency is measured by the Nusselt number that is defined as the heat transport in the presence of convection divided by the

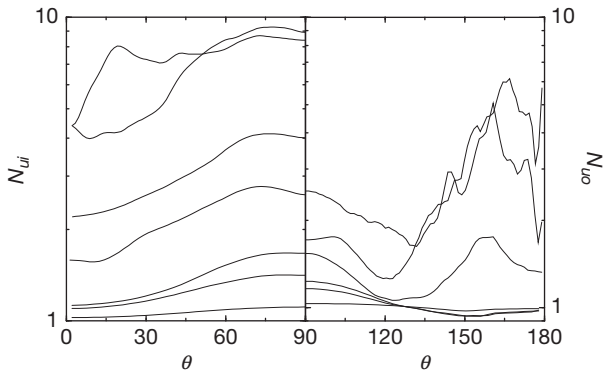

Figure 5 The time-averaged and azimuthally averaged local Nusselt numbers at the inner spherical boundary *Nu_i* (left plot) and at the outer spherical boundary *Nu_o* (right plot) as functions of the colatitude θ for $P = 0.5$, $\tau = 1.5 \times 10^4$, and $R = 4$, 8, 10, 15, 20, 30, 25×10^5 (from bottom to top at 90°).

heat transport in the absence of motion. In the case of the spherical fluid shell, two Nusselt numbers can be defined measuring the efficiency of convection at the inner and the outer boundary:

$$Nu_i = 1 - \frac{P}{r_i}\frac{d\overline{\overline{\Theta}}}{dr}\bigg|_{r=r_i} \qquad Nu_o = 1 - \frac{P}{r_o}\frac{d\overline{\overline{\Theta}}}{dr}\bigg|_{r=r_o} \qquad [16]$$

where the double bar indicates the average over the spherical surface. In addition, local Nusselt numbers

$$Nu_i(\theta) = 1 - \frac{P}{r_i}\frac{d\overline{\Theta}}{dr}\bigg|_{r=r_i} \qquad Nu_o(\theta) = 1 - \frac{P}{r_o}\frac{d\overline{\Theta}}{dr}\bigg|_{r=r_o} \qquad [17]$$

are of interest where only the azimuthal average is applied, as indicated by the single bar, instead of the average over the entire spherical surface. Examples of such measures of the dependence of the heat transport on latitude are shown in Figure 5. This figure demonstrates that at low supercritical Rayleigh numbers, the heat transport occurs primarily across the equatorial region, but as R increases, the heat transport in the polar regions takes off and soon exceeds that at low latitudes. This process is especially evident at the outer boundary. In the polar regions, convection is better adjusted for carrying heat from the lower boundary to the upper one, and it is known from computations of the convective heat transport in horizontal layers rotating about a vertical axis that the value of Nu may exceed the value in a nonrotating layer at a given value of R in spite of the higher critical Rayleigh number in the former case (Somerville and Lipps, 1973; Stevens et al., 2011).

Outside the tangent cylinder, the convective heat transport encounters unfavorable conditions in that the cylindrical form of the convection eddies is not well adjusted to the spherical boundaries. This handicap is partly overcome through the onset of time dependence in the form of vacillations in which the convection columns expand and contract in the radial direction or vary in amplitude.

At Prandtl numbers of the order unity and less, another effect restricts the heat transport. The shear of the geostrophic differential rotation created by the Reynolds stresses of the convection columns severely inhibits the heat transport. To

illustrate this effect, we have plotted in Figure 6 in addition to the Nusselt numbers the averages of the kinetic energy densities of the various components of the convection flow, which are defined by

$$\overline{E}_{\rm p}=\frac{1}{2}\left\langle\left|\nabla\times\left(\nabla\overline{\Phi}\times r\right)\right|^2\right\rangle,\quad \overline{E}_{\rm t}=\frac{1}{2}\left\langle\left|\nabla\overline{\Psi}\times r\right|^2\right\rangle \qquad [18a]$$

$$E_{\rm p}=\frac{1}{2}\left\langle\left|\nabla\times\left(\nabla\overset{\vee}{\Phi}\times r\right)\right|^2\right\rangle,\quad \overset{\vee}{E}_{\rm t}=\frac{1}{2}\left\langle\left|\nabla\overset{\vee}{\Phi}\times r\right|^2\right\rangle \qquad [18b]$$

where the angular brackets indicate the average over the fluid shell and $\overline{\Phi}$ refers to the azimuthally averaged component of Φ, while $\overset{\vee}{\Phi}$ is defined by $\overset{\vee}{\Phi}=\Phi-\overline{\Phi}$. Analogous definitions hold for the energy densities of the magnetic field where E, Φ, and Ψ are replaced by M, h, and g, respectively. The total magnetic energy density M averaged over the fluid shell is thus given by $M=\overline{M}_{\rm p}+\overline{M}_{\rm t}+\overset{\vee}{M}_{\rm p}+\overset{\vee}{M}_{\rm t}$.

Figure 6 is instructive in that it demonstrates convection both in the presence and in the absence of its dynamo-generated magnetic field. As is evident from the right part of Figure 6 with $M\sim 0$, relaxation oscillations occur in which convection sets in nearly periodically for short episodes once the energy $\overline{E}_{\rm t}$ of the differential rotation has decayed to a sufficiently low amplitude. But as soon as convection grows in amplitude, the differential rotation grows as well and shears off the convection columns. After convection has stopped, the differential rotation decays on the viscous timescale until the process repeats itself.

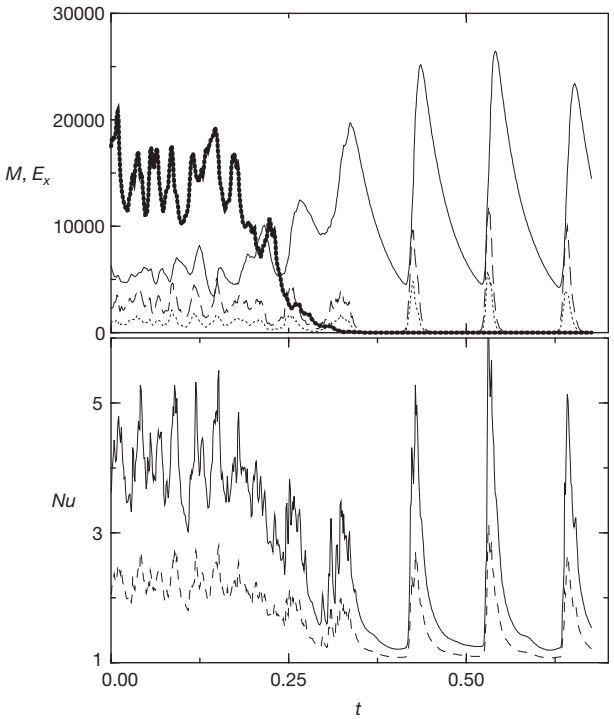

Figure 6 *Decay of a dynamo for* $P=0.5$, $\tau=1.5\times10^4$, $R=1.2\times10^6$, and $P_{\rm m}=0.5$. The total magnetic energy density M (thick dotted line, multiplied by a factor of 5), the kinetic energy densities $\overline{E}_{\rm t}$ (solid line), $\check{E}_{\rm p}$ (dotted line), $\check{E}_{\rm t}$ (dashed line), and the Nusselt numbers Nu_i (solid line) at the inner spherical boundary and Nu_o (dashed line) at the outer spherical boundary (lower plot) are plotted as functions of time t.

As long as the magnetic field is present, $\overline{E}_{\rm t}$ is suppressed owing to the action of the Lorentz force and high Nusselt numbers are obtained. In a nutshell, Figure 6 thus demonstrates why planets and stars require dynamos. Without them, they would not get rid of their heat in an efficient way due to the constraints of rotation.

It is worth pointing out that the dynamo-generated magnetic field acts in a fashion quite different from that of an imposed homogeneous field, which typically counteracts the effects of rotation and tends to minimize the critical value of the Rayleigh number when the Elsasser number,

$$\Lambda=\frac{2MP_{\rm m}}{\tau} \qquad [19]$$

assumes the value 1 in the case of a plane layer (Chandrasekhar, 1961) or values of the same order in the case of a sphere (Fearn, 1979) or in the related annulus problem (Busse, 1983).

10.07.5 Convection-Driven Dynamos

It appears that dynamos are generated by convection in rotating spherical shells for all parameter values as long as the magnetic Reynolds number is of the order 50 or higher and the fluid is not too turbulent. Since Rm can be defined by $P_{\rm m}\sqrt{2E}$ where the kinetic energy density, $E=\overline{E}_{\rm p}+\overline{E}_{\rm t}+\overset{\vee}{E}_{\rm t}+\overset{\vee}{E}_{\rm t}$, increases with R, increasing values of the Rayleigh number are required for dynamos as $P_{\rm m}$ decreases. In planetary cores, the latter parameter may assume values as low as 10^{-5} or 10^{-6}, but numerical simulations have achieved so far only values somewhat below 10^{-1}. The trend of increasing R with decreasing $P_{\rm m}$ is evident in Figure 7 where results are shown for two different values of τ and P. It is also evident from the results in the upper left corner of the figure that an increasing R may be detrimental for dynamo action. This is a typical property of marginal dynamos at the boundary of dynamos in the parameter space

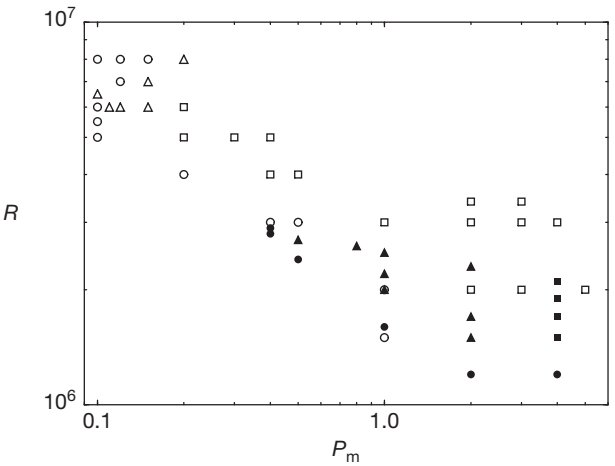

Figure 7 Convection-driven dynamos as a function of the Rayleigh number R and the magnetic Prandtl number $P_{\rm m}$ for $P=0.1$, $\tau=10^5$ (empty symbols) and for $P=1$, $\tau=3\times10^4$ (filled symbols). The symbols indicate chaotic dipolar (squares), hemispheric (triangles), and decaying dynamos (circles).

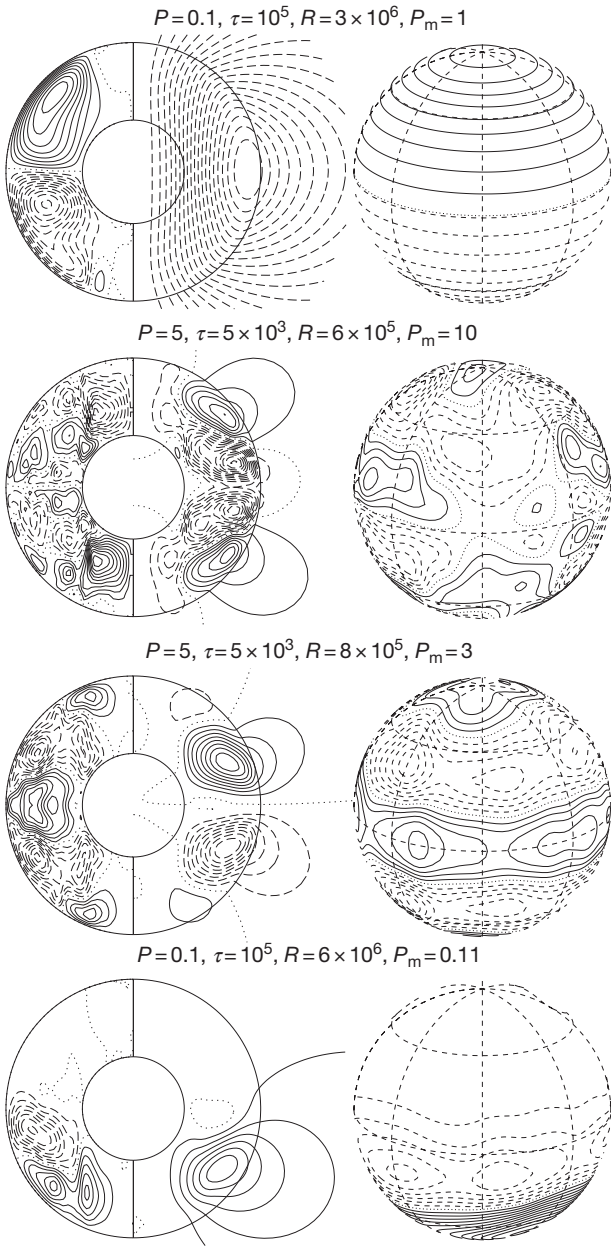
(Christensen et al., 1999; Simitev and Busse, 2005). Since convection at the relevant values of R is chaotic, this property also holds for the generated magnetic field. The magnetic energy must be finite near the boundary of dynamos in the parameter space because a sufficient amplitude of the fluctuating components of the convection flow can be obtained only when the magnetic field is strong enough to suppress the differential rotation. This property appears to hold even at high Prandtl numbers where differential rotation occurs only in the form of a relatively weak thermal wind.

Even in its chaotic state, convection at high values of τ exhibits a strong symmetry with respect to the equatorial plane at high values of τ, at least as long as convection in the polar regions is still weak. Because of this symmetry, either magnetic fields can be generated with the same symmetry as the convection flow, that is, h and g are antisymmetric with respect to equatorial plane in which case one speaks of a quadrupolar dynamo, or the magnetic field exhibits the opposite symmetry with symmetrical functions h and g in which case one speaks of a dipolar dynamo. Of special interest are hemispheric dynamos (Grote and Busse, 2001) in which case the fields of dipolar and quadrupolar symmetry have nearly the same amplitude such that they cancel each other either in the Northern or in the Southern Hemisphere. Examples of typical dynamos with different symmetries are shown in Figure 8. Here, it is also evident that low P and high P dynamos differ in the structure of their mean toroidal fields. While their mean poloidal dipolar fields exhibit hardly any difference, the high P dynamo is characterized by strong polar azimuthal flux tubes that are missing in the low P case. The reason for this difference is that the radial gradient of the differential rotation in the polar regions is much stronger for high P than for low P.

As the Rayleigh number increases and polar convection becomes stronger, the convection flow loses some of its equatorial symmetry and the magnetic field can no longer easily be classified. Usually, the dipolar component becomes more dominant in cases of dynamos that started as either quadrupolar or hemispheric dynamos at lower values of R.

It should be emphasized that quadrupolar and hemispheric dynamos are usually oscillatory in that new azimuthal flux tubes of alternating sign emerge in the equatorial plane and move towards higher latitudes, while old flux tubes are dissipated in the polar region. There also exist dipolar dynamos that exhibit the same type of oscillations. They are typically found in the parameter space near the region where hemispheric dynamos occur. To illustrate the dynamo oscillations, additional plots separated at equal distances in time before the corresponding plot in the lower three rows of Figure 8 are shown in Figure 9. The four plots in each case cover approximately half a period of oscillation. It must be realized, of course, that the oscillations are not strictly periodic since they occur in a turbulent system. In this respect, they resemble the solar cycle with its 22-year period. Because the solar dynamo is believed to operate at the bottom of the solar convection zone, the propagation of the dynamo wave is towards low latitudes on the sun. A remarkable feature of the dipole oscillation in Figure 9 is that the polar flux tubes hardly change in time. The oscillation appears to be confined to the region outside the tangent cylinder. At a lower value of P_m, the strong polar flux tubes even inhibit the oscillation of the mean poloidal field as



$P=0.1,\ \tau=10^5,\ R=3\times10^6,\ P_m=1$
$P=5,\ \tau=5\times10^3,\ R=6\times10^5,\ P_m=10$
$P=5,\ \tau=5\times10^3,\ R=8\times10^5,\ P_m=3$
$P=0.1,\ \tau=10^5,\ R=6\times10^6,\ P_m=0.11$

Figure 8 Various types of dynamo symmetry. The left column shows lines of $\overline{B}_\varphi = \text{const.}$ (left half) and $r\sin\theta\partial_\theta\overline{h} = \text{const.}$ (right half). The right column shows surfaces of $B_r = \text{const.}$ at $r = r_o + 0.7$.

shown in Figure 10. This case has been called the 'invisibly' oscillating dynamo since at some distance from the boundary of the spherical fluid shell, the oscillation of the dynamo can hardly be noticed.

The relatively simple magnetic fields displayed in Figures 8–10 should not be regarded as representative for high values of the Rayleigh number when R exceeds its critical value R_c by an order of magnitude or more. In that case, the equatorial symmetry has nearly disappeared owing to the dominant convection in the polar regions, and nonaxisymmetric components of the field tend to exceed axisymmetric ones as shown, for example, in Figure 11. The strong growth with

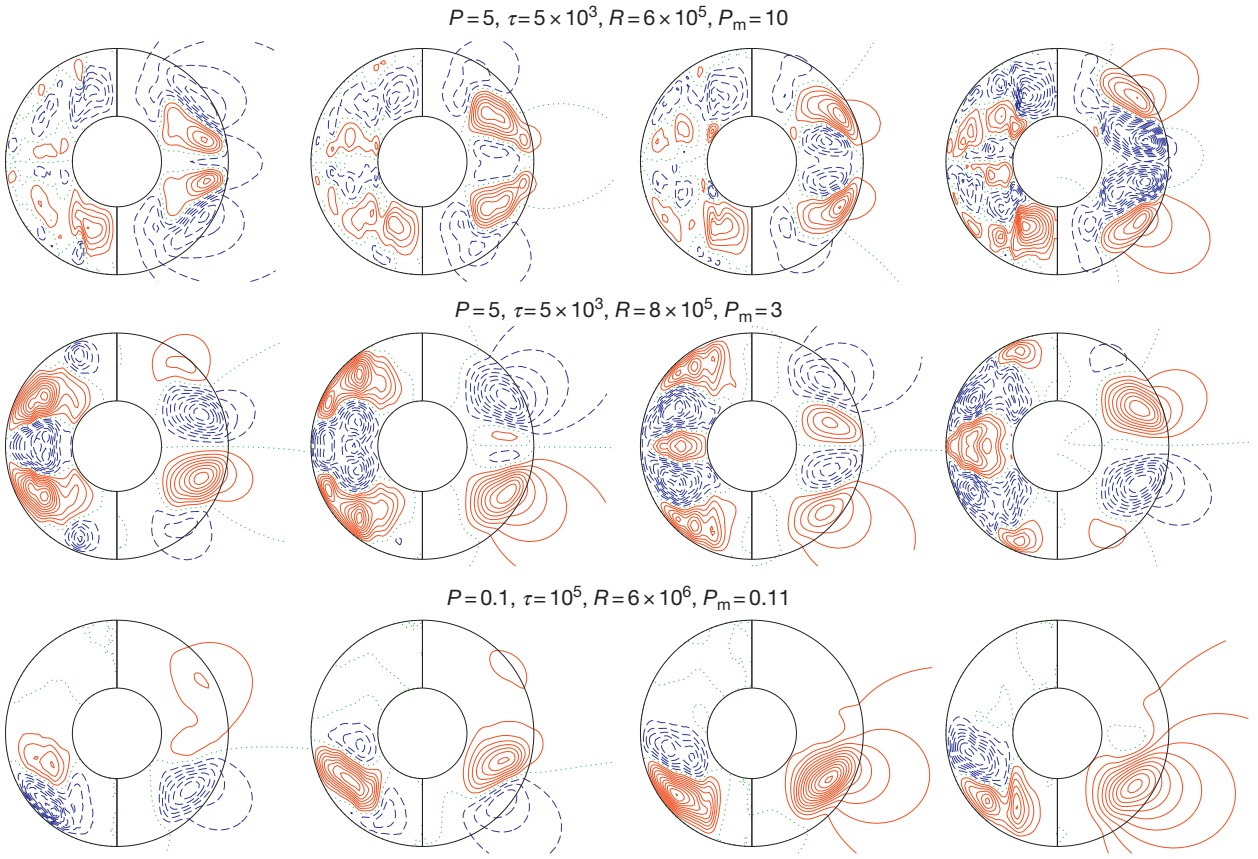


Figure 9 Plots for the last three cases of **Figure 8** at the times $n\cdot\Delta t$, $n=3, 2, 1, 0$ (left to right), before the times of **Figure 8** where $\Delta t=0.035$, 0.04, and 0.0025 (from top to bottom) has been used.

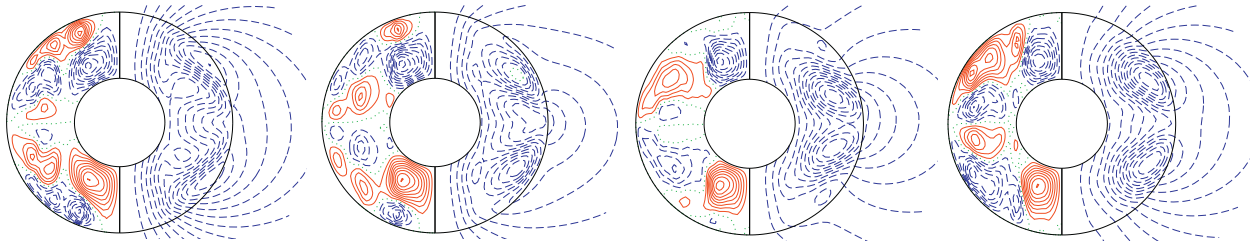

Figure 10 An 'invisibly' oscillating dynamo with $\Delta t=0.04$ in the case of $P=P_m=5$, $\tau=5\times10^3$, and $R=6\times10^5$. The plots show lines of constant $\overline{B}_\varphi$ in their left halves and meridional field lines, $r\sin\theta\partial_\theta\bar{h}=$ const., in their right halves. Δt represents about a quarter of a cycle.

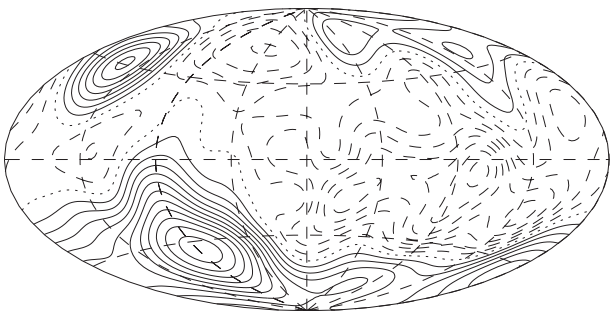

Figure 11 Lines of constant B_r at $r=r_o+1$ for the dynamo with $R=2\times10^6$, $\tau=5\times10^3$, and $P=P_m=1$.

increasing Rm of the nonaxisymmetric magnetic flux is also evident in **Figure 12** when energies corresponding to different values of P_m are compared.

An important question is the average strength of the magnetic field generated by the dynamo process in dependence on the parameters. Two concepts are often used in attempts to answer this question. In astrophysical situations, the equipartition between magnetic energy and kinetic energy is used as a guide. While such a balance may hold locally as, for example, in the neighborhood of sunspots, it is not likely to be applicable to global planetary magnetic fields. In the Earth's core, for example, the magnetic energy density exceeds the kinetic one by a factor of the order of 10^3.

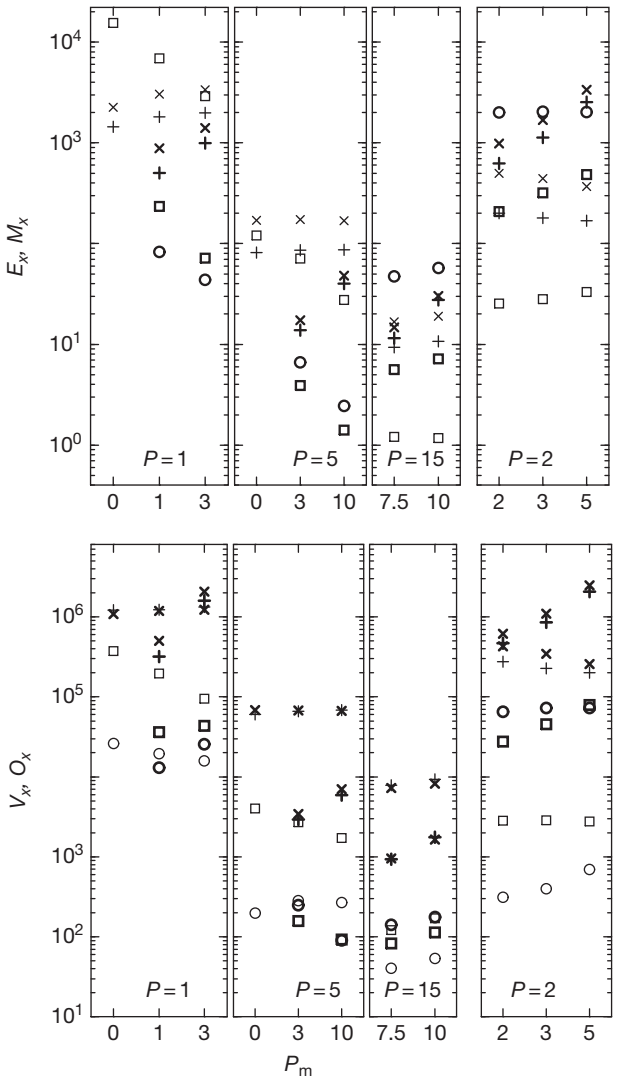

Figure 12 Kinetic E_x and magnetic M_x energy densities (upper part) and viscous V_x and Ohmic O_x dissipations (lower part) as functions of P_m for convection-driven dynamos for $\tau=5\times10^3$, $R=10^6$ (left three columns), $\tau=3\times10^4$, and $R=3.5\times10^6$ (right column) and the Prandtl number as indicated in the boxes. The highest values of the Elsasser number for the cases $P=1$, 5, 15, and 2 are $\Lambda=3.02$, 0.37, 0.49, and 1.12, respectively. The components $\overline{X}_p, \overline{X}_t, \widetilde{X}_p, \widetilde{X}_t$ (where X = E, M, V, O) are represented by circles, squares, plus-signs, and crosses, respectively. Kinetic energy densities and viscous dissipations are shown with light symbols; magnetic energy densities and Ohmic dissipations are shown with heavy symbols. The magnetic Prandtl numbers $P_m=0$ correspond to nonmagnetic convection.

A second concept is based on the property that an Elsasser number Λ of the order unity appears to correspond to optimal conditions for convection in rotating systems in the presence of an applied nearly uniform magnetic field. While this idea may be useful as a first rough estimate, the results of numerical dynamo simulations do not really support this concept. The examples shown in Figure 12 exhibit Λ-values differing by an order of magnitude, and even larger variations have been reported by Simitev and Busse (2005) and by Christensen and Aubert (2006). For a critical assessment of the use of the Elsasser number, see Soderlund et al. (2012). It should also be kept in mind that at the same conditions, two distinct types of dynamos may exist that exhibit vastly different mean dipolar fields (Simitev and Busse, 2009, 2012).

The large number of computationally generated convection-driven dynamos has allowed Christensen and Aubert (2006) to obtain a scaling relationship for the strength B of the magnetic field that no longer depends on the rate of rotation Ω but instead depends only on the available power for driving the dynamo. They analyze their data in terms of parameters such as the Rayleigh number, Nusselt number, and the dimensionless buoyancy flux $\hat{Q}$ that are defined through quantities that no longer involve molecular diffusivities. This procedure requires the presence of rotation and cannot be achieved in a non-rotating system. It finally leads to the scaling relationship

$$B^2 \propto \rho r_o^{4/3} \hat{Q}^{2/3} \qquad [20]$$

for the magnetic energy density in the dynamo region that fits the available numerical data for sufficiently high rates of rotation quite well. For a more detailed discussion of scaling laws, see Jones (2011).

The brief introduction of this section to convection-driven dynamos in rotating spherical fluid shells can only give a vague impression of the potential of numerical simulations for the understanding of planetary magnetism. Many more examples of such simulations can be found in the literature. Usually, they have been motivated by applications to the geodynamo, and $P=1$ is assumed in most cases for simplicity. For some recent systematic investigations, we refer to Christensen et al. (1999), Grote et al. (2000), Jones (2000), Grote and Busse (2001), Kutzner and Christensen (2000, 2002), Busse et al. (2003), Simitev and Busse (2005), Aubert et al. (2009), and other papers referred to therein.

10.07.6 Applications to Planetary Dynamos

10.07.6.1 General Considerations

Although numerical simulations of the kind discussed in the preceding sections are still rather removed from the parameter regime relevant to planetary interiors, numerous dynamo models with modified boundary conditions or including regions of stably stratified density have been applied with some success to planetary situations. Properties such as compressibility and other deviations from the Boussinesq approximation that so far have been considered only in special models applied to the Earth's core (Glatzmaier and Roberts, 1996) or to the sun (Brun et al., 2004) are beginning to be taken into account for dynamo models of the giant planets. In this respect, the benchmark for anelastic convection and dynamos (Jones et al., 2011) is of interest.

Many essential parameter values of planetary cores are not sufficiently well known, however, to provide a basis for the development of more specific dynamo models. Much of the future progress of the field will thus depend on the mutual constraints derived from observational evidence and from theoretical conclusions in order to arrive at a better understanding of the workings of planetary dynamos.

In Table 2, some properties related to planetary magnetism have been listed. The dipole moments of the planets have been given as multiples of $G \cdot R_p^3$ where R_p denotes the mean radius of the planet or satellite. Thus, the numerical value indicates the field strength in *gauss* in the equatorial plane of the dipole at the distance R_p from its center. We have included Mars in the table, although it does have an active dynamo at the present time. The strong magnetization of the Martian crust indicates, however, that a strong field dynamo must have operated in the early history of the planet (see also **Chapter 10.06**).

The most important question of the theory of planetary magnetism is the dependence of the observed field strength on the properties of the planet. We have already discussed in the historical introduction various proposals for such dependences based on ad hoc assumptions, but these have been abandoned by and large. Only the concept of an Elsasser number Λ of the order unity is still frequently used. Stevenson (2003) showed that a value $\Lambda = 0.3$ fits most of the planets with a global magnetic field quite well, but in cases such as Mercury and Saturn, only a value of the order 10^{-2} can be estimated for Λ. In order to save the concept, different dynamo regimes must be assumed. Equilibration balances for weaker magnetic fields have been proposed as, for instance, in the case when the strength of convection is not sufficient to attain the $\Lambda \sim 1$ balance. For details, see Stevenson (1984).

An important balance often invoked in discussions of planetary dynamos (see, e.g., Jones, 2003; Stevenson, 1979) is the MAC balance (Braginsky, 1967) where it is assumed that Lorentz force, buoyancy force, and pressure gradient are all of the same order as the Coriolis force, while viscous friction and the momentum advection term are regarded as negligible in the equations of motion. The neglect of the latter term is well justified for high Prandtl numbers, but it is doubtful for values of P of the order unity or less. In spite of their smallness in comparison with the Coriolis force, the divergence of the Reynolds stress can generate the most easily excitable mode of a rotating fluid, namely, the geostrophic differential rotation, which cannot be driven by the Coriolis force, the pressure gradient, or buoyancy. Of course, an excitation by the Lorentz force is possible in principle. The latter force, however, usually inhibits the geostrophic differential rotation. Since the mean azimuthal component of the magnetic field is typically created through the shear of the differential rotation, the Lorentz force opposes the latter according to Lenz's rule.

The prediction [20] of Christensen and Aubert (2006) for the strength of the magnetic field in the dynamo region fits the cases of the Earth and Jupiter quite well but yields the result that Mercury's field could not be generated by a buoyancy-driven dynamo since the magnetic Reynolds number would be too small. In the cases of the outer planets, relevant parameters are not sufficiently well known to draw definitive conclusions. The negative result in the case of Mercury may be misleading, however, since the observed field may not be representative for the dynamo-generated field inside the planet as will be discussed in **Section 10.07.6.2**.

Finally, we like to draw attention to what has been called Stevenson's paradox, that is, that a too high electrical conductivity is detrimental for dynamo action in planetary cores. According to the Wiedemann–Franz law of condensed matter physics, the thermal conductivity k of a metal is proportional to its electrical conductivity times the temperature, $k = \sigma TL$, where L has approximately the same value for all metals. This is due to the fact that in metals, electrons dominate the transports of both heat and charge. As a consequence, there is an upper bound on the electrical conductivity for which a dynamo driven by thermal convection is possible because a high value of σ implies a low temperature change with increasing depth needed to carry the heat from the interior of the planetary core. But as soon as the temperature change with pressure falls below its isentropic value, thermal convection disappears and a stably stratified environment is obtained, which makes it difficult to drive a dynamo by other types of motions such as compositional convection. Ignoring the latter possibility, Stevenson (2003) had sketched the diagram shown in **Figure 13** where the marginal nature of dynamos in terrestrial and in the 'icy' planets is indicated.

Related to Stevenson's paradox is the fact that regions of high electrical conductivity are not the most likely places where dynamos operate in the major planets. Magnetic field generation in deeper regions of Jupiter and Saturn would lead to an Ohmic dissipation exceeding the luminosity of these planets, as has been emphasized by Liu et al. (2008). It thus appears

Table 2 Planetary parameter values

Planet (satellite)	*Planetary radius*, R_p ($\times 10^6$ m)	*Dipole moment* ($\times 10^{-4}$ T $\times R_p^3$)	*Core radius* ($\times 10^6$ m)	*Angular rate of rotation*, Ω ($\times 10^{-5}$ s^{-1})	*Magnetic diffusivity* (m^2 s^{-1})
Mercury	2.439	0.0025	2.0	0.124	~2
Earth	6.371	0.31	3.48	7.29	2
Mars	3.389	3[a]	~1.5	7.08	~2
Jupiter	69.95	4.3	60[b]	17.6	100[b]
Saturn	58.30	0.21	35[b]	16.2	100[b]
Uranus	25.36	0.23	17[b]	10.1	100[b]
Neptune	24.62	0.14	18[b]	10.8	100[b]
Ganymede	2.63	0.0072	0.7	1.02	4

[a]Remnant magnetism of the Martian crust appears to require an ancient dynamo with a field strength of at least ten times the Earth's magnetic field.
[b]Since the giant planets do not possess a well-defined boundary of a highly conducting core, values of the most likely region of dynamo activity are given.

likely that the dynamos of these planets operate in regions where hydrogen is still a semiconductor. For more details, we refer to the review of Stanley and Glatzmaier (2010).

In the following, brief characterizations of the magnetisms of various planets and moons are given. In terrestrial planets and satellites, dynamos are possible in the liquid parts of their iron cores. Such cores always include light elements that depress the temperature of freezing and can give rise to compositional buoyancy since they stay in solution while a solid inner core is growing. In Jupiter and especially in Saturn, convection may also be driven in part by compositional buoyancy since hydrogen and helium are immiscible in certain regions and helium drops may rain out. In numerical dynamo models, the different sources of buoyancy are usually not distinguished, however.

10.07.6.2 Mercury

It has already become apparent that the origin of Mercury's magnetism is especially enigmatic. Besides the hypothesis of an active dynamo, thermoelectric currents and remnant magnetism of the crust compete as explanations. The latter possibility had been discarded for a long time since Runcorn's theorem states that a homogeneous spherical shell cannot be magnetized by an interior magnetic field in such a way that a dipolar field can be observed from the outside after the interior source has been removed (Runcorn, 1975). Aharonson et al. (2004) had shown, however, that plausible inhomogeneities of the crust could possibly explain a remnant magnetic field created by an ancient dynamo.

The idea that a convection-driven dynamo operates in a fluid outer core of Mercury has received some support from observations of Mercury's librations (Margot et al., 2004). The amplitudes of the small periodic variations (librations) of Mercury's rotation caused by the gravitational pull of the sun on the nonaxisymmetric mass distribution of Mercury appear to be too large for a fully solidified planet. This suggests that the solid inner core is separated from the mantle by a fluid outer core in which convection flows may occur.

According to Williams et al. (2007), a present-day dynamo in Mercury is difficult to achieve because of possibly insufficient heat sources for driving convection. Nevertheless, numerous dynamo models have been proposed, which attempt to explain the rather low amplitude of the Hermian magnetic field. The numerical simulations by Stanley et al. (2005) of dynamos in a thin shell liquid outer core have demonstrated that the dipole strength measured from the outside may not be representative for the strength of the magnetic field at the core–mantle boundary and the criteria mentioned in **Section 10.07.6.1** may be satisfied after all. Christensen (2006) and Christensen and Wicht (2008) advocated a stably stratified outer part of the liquid outer core that effectively damps the field generated by convection in the inner part of the liquid outer core. The model has recently been improved by Manglik et al. (2010) who have taken into account compositional and thermal buoyancy separately. When the compositional buoyancy plays a minor role, it can be demonstrated that Mercury's dynamo may fit the scaling relationship [20] of Christensen and Aubert (2006).

Heyner et al. (2011) showed through numerical simulations that a negative feedback between the magnetospheric and the internal magnetic fields can exist, which would dampen the latter. The question, however, whether there is a sufficiently strong source of buoyancy to sustain convection and the dynamo over the age of the planet has not yet been answered satisfactorily.

The recent measurements of the MESSENGER spacecraft have permitted a much improved determination of Mercury's magnetic field. It resembles a nearly axisymmetric dipole field but with a dipole origin displaced northward from the center of the planet such that the field strength at the North Pole exceeds that at the South Pole by a factor of 3.4 (Anderson et al., 2011). Such a configuration may remind one of a hemispheric dynamo as discussed in the context of **Figures 8** and 9.

10.07.6.3 Venus

Space probes have clearly shown that presently, there is no dynamo operating in Venus. This result is surprising since Venus is very similar to the Earth in many other aspects. That the period of rotation is only 1/243 of a day should not matter much since the Coriolis parameter τ is still huge. More important is the fact that the cooling of the planet is less efficient because of the apparent absence of mantle convection and plate tectonics. As model calculations by Stevenson et al. (1983) have shown, the existence of a dynamo in the core of a terrestrial planet depends sensitively on the thermal history of the planet. In Venus, a solid inner core may not yet have started to grow, and sufficiently vigorous convection does not seem to occur in the core, at least not at the present time. Venus could have had a dynamo in the past, perhaps until 1.5 Gy ago, and a future dynamo may well be possible.

10.07.6.4 Mars

Mars does not have an active dynamo, but the strong magnetization of parts of the Martian crust in its Southern Hemisphere requires a field of at least ten times the strength of the present geomagnetic field. The observed north–south dichotomy of the Martian crustal magnetization has given rise to rather different theoretical explanations. According to Milbury and Schubert (2010), large parts of the originally fairly homogeneously magnetized crust have later been demagnetized or removed through impacts. On the other hand, the asymmetry of the magnetization could be a consequence of an asymmetry of the convection flows in the Martian iron core (Stanley et al., 2008). Amit et al. (2011) demonstrated with their dynamo models that a moderate heat flux anomaly caused by a mantle heterogeneity at the geographic pole may be sufficient to produce the magnetization dichotomy. There is general agreement that the Martian dynamo operated before 4 Gy ago (Lillis et al., 2008). It may have been stopped by a giant impact heating the Martian core through shock waves (Arkani-Hamed and Olson, 2010). Other authors argue that the Martian dynamo operated in the Noachian period (about 4.1–3.7 Gy ago) and perhaps even beyond that time. See discussion by Schubert and Soderlund (2011).

10.07.6.5 Moon

Like Mars, the Moon does not have an active dynamo, but the magnetization of the lunar crust detected by the Apollo subsatellites and the paleomagnetic analysis of lunar rocks indicate that a dynamo has been operating, at least intermittently, in the time span between 4.2 and 3.7 Gy ago (Shea et al., 2012). The rather small size of the lunar iron core with a radius of about 350 km suggests that a convection-driven dynamo operating throughout a period of 500 My is rather unlikely. An alternative possibility is an intermittently operating dynamo driven by motions in the liquid lunar core generated by major impacts (Dwyer et al., 2011; Le Bars et al., 2011).

10.07.6.6 Jupiter

The Jovian magnetic field is rather similar to the geomagnetic one sharing with it a dipole axis that is inclined by an angle of the order of 10° with respect to the axis of rotation. That the higher harmonics of the field are relatively stronger than those in the case of the Earth suggests that the Jovian dynamo is driven at a more shallow layer than the Earth's outer core. This assumption is in accordance with the transition to metallic hydrogen, which is expected to occur at a pressure of 140 GPa corresponding to a depth of about 15% of the Jovian radius (Nellis et al., 1996). The transition is not a sharp one as suggested by earlier models of Jupiter's interior, but a gradual one leading to a decrease of the magnetic diffusivity down to about 4 $m^2\,s^{-1}$. Since this value yields a rather high value for the Elsasser number Λ, Stevenson (2003) had argued that the dynamo is most active above the region of highest conductivity. Jones (2003), on the other hand, accepted the value 20 for Λ but must admit a high magnetic Reynolds number of the order 10^4 at which an effective dynamo may no longer be possible.

A detailed model of a convection-driven Jovian dynamo should include effects of compressibility and depth-dependent electrical conductivity. A first attempt in this direction has most recently been published by Duarte et al. (2013). In this paper, the somewhat controversial ideas about the penetration of the surface differential rotation into the Jovian interior and the location of dynamo action are also discussed.

10.07.6.7 Saturn

Saturn's magnetic field with a strength of 0.2 mT near the poles is much weaker than that of Jupiter, which must be attributed primarily to its deeper origin in the planet. The transition pressure of 140 GPa is reached only at a depth of about 40% of the planetary radius. A property that has received much attention is that the Saturnian magnetic field is nearly axisymmetric with respect to the axis of rotation. This property cannot be interpreted as a contradiction to Cowling's (1934) theorem since it has long been shown that fields with arbitrarily small deviations from axisymmetry can be generated by the dynamo process (Braginsky, 1976). Stevenson (1982) gave an explanation for the almost axisymmetric Saturnian field by demonstrating that the differential rotation in the stably stratified but still electrically conducting gas shells above the dynamo region will tend to shear off all nonaxisymmetric components of the field. The problem may be a bit more intricate, as has been pointed out by Love (2000) who showed that sometimes, fields with solely nonaxisymmetric components are found in such situations.

10.07.6.8 Uranus and Neptune

A metallic liquid probably does not exist in Uranus and Neptune whose interiors consist mostly of ice and rocks. Because of the pressure dissociation of water, it is believed that deeper regions of these planets are characterized by an ionic conductivity that is lower than typical metallic conductivities by between one and two orders of magnitude. Recent laboratory measurements (Lee et al., 2006) suggest, however, that water is semiconducting at pressures of 100 GPa and relevant temperatures of the order of 4000 K. The mixture of water, methane, ammonia, and other ices is sufficiently fluid that convection can occur and that a dynamo is thus possible. The fact that the observed magnetic fields do not show an alignment with the axis of planetary rotation and that quadrupolar and octupolar components are comparable to the dipolar components of the fields has been attributed to a dynamo operating in a thin shell (Ruzmaikin and Starchenko, 1991; Stanley and Bloxham, 2004). This seems to be hardly necessary, however, since convection-driven dynamos in thick shells often exhibit quadrupolar or hemispheric structures (Grote and Busse, 2001; Grote et al., 2000). In particular, such fields are found when small-scale components dominate as in the case of high Rayleigh numbers and low Prandtl numbers. See, for example, **Figure 11** that shows a magnetic field rather similar to that of Uranus as displayed in the paper of Connerney (1993). A special difficulty for a convection-driven dynamo in the interior of Uranus is caused by its low emission of heat. Holme and Bloxham (1996) suggested that a typical dynamo would involve more Ohmic dissipation than that corresponds to the heat flux emitted from the interior of the planet.

10.07.6.9 Ganymede and Other Satellites

It came as a great surprise when the measurements by the Galileo spacecraft indicated that Jupiter's moon Ganymede possesses a global magnetic field for which an active dynamo inside the satellite seems to be the only realistic explanation (Kivelson et al., 1996). The only competing explanation that cannot easily be excluded is remnant magnetism (Crary and Bagenal, 1998). It must be kept in mind that Ganymede is the largest satellite in the solar system, which exceeds even Mercury in size. Nevertheless, the estimated radius of its iron core is only about 660 km, and it is hard to believe that sufficiently strong convection could still exist in the core unless it contains a lot of radioactive potassium 40. Even a capture of Ganymede into a resonance in its more recent history would not have supplied sufficient heating (Showman and Malhotra, 1999). But see also the discussion by Breuer et al. (2010).

The fact that Ganymede's magnetic moment is nearly aligned with the ambient Jovian magnetic field has led to the suggestion that this field could aid significantly Ganymede's dynamo. But Sarson et al. (1997) had investigated this question with the result that the ambient field is too weak to exert much influence.

In the case of Io that is much closer to Jupiter, the ambient Jovian field could eventually aid a dynamo, but there is no need for such an assumption since the observations obtained by the Galileo spacecraft can readily be explained by the interaction of the Jovian field with the hot electrically conducting interior of Io (Khurana et al., 2011).

There are no other satellites in the solar system where an active dynamo must be suspected. The substantial magnetization of many meteorites suggests, however, that several differentiated protoplanets have had dynamos in the early days of the solar system. This fact is also supported by the remanent magnetism that has been measured at several asteroids.

10.07.7 Concluding Remarks

It is apparent from the discussions in the preceding text that dynamo theory does not yet have much specific information to contribute to the interpretation of the observed magnetic properties of planets and satellites in the solar system. Even possible interactions between thermal and compositional buoyancies have not yet been taken fully into account (Breuer et al., 2010; Busse, 2002b; Glatzmaier and Roberts, 1996; Simitev, 2011). Some typical properties are already apparent, however, such as the following:

- Dynamos that are dominated by a nearly axial dipole and exhibit a magnetic energy that exceeds the kinetic one by orders of magnitude as in the case of the Earth are typical for highly effective Prandtl numbers as must be expected when convection is primarily driven by compositional buoyancy. The rather Earth-like appearance of the dynamo of Glatzmaier and Roberts (1995) is in part due to the high value of P used in their computational model.
- Dynamos exhibiting strong higher harmonics are more likely driven by thermal convection corresponding to the Prandtl numbers of the order unity or less.
- Dynamo oscillations are a likely phenomenon in the presence of a sufficiently strong differential rotation. They may not always be apparent in the poloidal magnetic field observed at a distance from the dynamo region.
- Considerations based on the effects on convection of an imposed homogeneous magnetic field cannot directly be applied to the case of convection-driven dynamos.

More details on the parameter dependence of dynamos will certainly emerge in the future as the increasingly available computer capacity will allow extensions of the parameter space accessible to computer simulations. Future space probes will provide much needed detailed information on planetary magnetic fields. Eventually, we may learn more about their variation in time, which is one of the most interesting properties of planetary magnetic fields.

As in the case of stellar magnetism where the study of star spots and stellar magnetic cycles is contributing to the understanding of solar magnetism, it may eventually become possible to learn about the magnetism of extrasolar planets and apply this knowledge for an improved understanding of solar system dynamos. Undoubtedly, the field of planetary magnetism will continue to be an exciting one!

10.08.1 Introduction

Unraveling a terrestrial planet's evolution in order to understand the observed processes and features is a difficult task that requires the integration of evidence from a wide variety of fields into consistent models. Geology, geophysics, mineralogy, and cosmochemistry, as well as chemistry, physics, and even biology, all influence the thermal and chemical evolution of terrestrial bodies. Our knowledge of the other terrestrial bodies stems not only mostly from remote sensing satellites but also, in some cases, from in situ chemical measurements and even from surface samples, in the case of the Moon, and meteorites – in the case of the Moon and Mars. These samples have been of immense value for the Moon and Mars science as they provide information not only about the composition but also about processes such as the formation of the core and the crust of those bodies. A fundamental process in planetary evolution is the thermal evolution of its interior, which depends on the internal heat sources, on thermophysical properties, and, to a large extent, on the dynamics of the planet's mantle through which heat is transported by thermal convection. It has been understood since the beginning of the twentieth century that thermal convection is capable of driving mantle circulation. If the mantle is heated from within (or from below) and is cooled from above, it can become gravitationally unstable and thermal convection can occur as colder

rock descends into the mantle and hotter rock ascends toward the surface. This circulation of material transports heat toward the planet's surface and tends to cool the interior, while heat produced within, for example, by the decay of radioactive elements, tends to warm it. The motions driven by convective heat transport result in surface stresses and deformation, producing many geologic features observed on the terrestrial bodies today. An understanding of planetary thermal evolution is critical for interpreting these surface features in terms of interior processes including the dynamics of the mantle and the core.

The plate tectonics of the Earth are a unique expression of mantle convection among the terrestrial planets. Our planet's otherwise stiff lithosphere is segmented by weak zones into distinct plates. Where plates diverge, new lithosphere is created, and where they converge, the lithosphere descends into the mantle. This recycling process transfers heat out of the interior very effectively. One consequence of this process is that the Earth has a very young oceanic crust, generally less than 200 million years old (e.g., Condie, 1997). In addition to the oceanic crust, a less dense continental crust exists that usually does not recycle into the interior and has an average age of about 2000 Ma (e.g., Kemp and Hawkesworth, 2003). Comparing the Earth with the other terrestrial planets, the most striking difference at first glance is the state of the surface (including the crust), which is indicative of the way heat is transported. The surfaces of other planets are not segmented but consist of single plates, the so-called stagnant lids, beneath which the mantle convects. Heat flow through the lid is mainly by conduction, with some minor contribution by volcanic heat transport through this stagnant lid. The difference in the heat transport mechanism for the planets is also reflected in their thermal evolution.

In this chapter, we describe the thermal evolution and the mantle dynamics and related processes like crustal formation and the magnetic field evolution of the terrestrial bodies other than the Earth, that is, Mercury, Venus, Mars, and the Moon. The Galilean satellite Io is included in this chapter since this body consists, like the terrestrial planets and the Moon, of an iron-rich core and a silicate outer shell. The close orbit about Jupiter and the resonant orbital interaction among Io, Europa, and Ganymede make Io, however, special among the other terrestrial bodies. In its interior, tidal deformation plays an important role and provides an extremely large internal heat source. The consequence is a very different thermal evolution for Io than for the other bodies; therefore, we discuss Io in a separate section of this chapter.

The chapter is organized as follows: First, we describe the relevant physical and chemical properties of planets and planetary materials bearing on mantle dynamics and thermal evolution models. In the next section, the concept of mantle convection is introduced and the relationships between the convective parameters and the planform of the flow are discussed. A description of parameterized convection models follows with a comparison of three main heat transport mechanisms: plate tectonics, stagnant lid convection, and lithosphere delamination. In the next section, the crustal formation and magnetic field generation of terrestrial planets are described since both strongly depend on the thermal evolution of a planet and can be used as constraints for the models. The chapter concludes with separate reviews of the thermochemical evolution and mantle dynamics of Mercury, Venus, the Moon, Mars, and Io and includes a summary section.

10.08.2 Physical and Chemical Properties of Planets and Planetary Materials Bearing on Mantle Dynamics and Thermal Evolution Models

10.08.2.1 Interior Structure and Phase Transitions

The interior dynamics and thermal evolution of the terrestrial planets depend strongly on internal structure and composition. One important characteristic is the size and density of the major reservoirs, that is, the core, mantle, and crust. Lacking seismic data for most bodies, the basic structure can be estimated from the mean density and the polar moment of inertia (MoI) factor of the terrestrial bodies. The latter parameter can be obtained from the measurements of the low-order gravity field (J_2 and C_{22}), the figure, and/or the precession rate of the planet. The use of shape or gravity data to infer the MoI requires a planet to be in hydrostatic equilibrium. The determination of the interior structure does not provide a unique solution; there is, for example, a trade-off between the core size and core density. However, with additional constraints on composition, it is possible to derive estimates of the structure (see **Chapter 10.02**). For mantle dynamics, the size of the metallic core is of particular interest. A large core (and hence a thin mantle) suggests less radiogenic heat sources (which tend to be found in the rock phase) and thus lower temperatures of the mantle layer, and one finds in general a convection pattern that is smaller in scale compared to a planet with a thick mantle.

Thermal convection can be strongly influenced by chemical layering and phase transitions in the mantle. In the case of chemical layering, density variations that influence convection are caused not only by temperature variations but also by differences in mantle composition. Chemical layering can block or retard mantle flow if the compositional density increases with depth. In this stable configuration, thermal convection is only possible if density changes due to temperature variations can overcome the compositional density differences. Chemical layering can enhance mantle flow if the compositional component of density decreases with depth. Reshuffling of this unstable configuration results in a stable density configuration unless efficient mixing prevents the establishment of distinct layers. It is also possible that thermal convection takes place in separate and chemically distinct layers. The heat transport in a mantle with layered thermal convection is less efficient than in a mantle with whole mantle convection (Spohn and Schubert, 1982). Chemical stratification resulting from early differentiation of the mantle is one way to explain the presence of separate and chemically distinct reservoirs that might be needed to explain geochemical observations. The density contrast between the layers must be sufficient to overcome the tendency of convective motions to mix the material at the boundary (Gurnis, 1986). At present, we do not know whether distinct chemical reservoirs other than the crust, mantle, and core exist in the terrestrial planets and the Moon.

Phase transitions in planetary mantles also play an important role in the dynamics and thermal evolution of the planet. At a certain pressure and temperature, mantle materials undergo isochemical phase changes, associated with a change in density. The variation of the phase transition temperature T with pressure P is related to the volume and entropy changes,

ΔV and ΔS, respectively, through the Clausius–Clapeyron equation ($dP/dT = \Delta S/\Delta V$). The phase change from olivine to spinel has a positive Clapeyron slope (also called exothermic phase transition in the literature). Thus, for downwelling cold material, the depth of the phase change is elevated, while for hot upwelling material, the boundary is deflected downward; both distortions cause an acceleration of the moving material. These distortions and therefore the acceleration of the flowing mantle material at the phase transitions are reduced by the release and consumption of latent heat for the rising and sinking material, respectively.

In the case of a negative Clapeyron slope as for the spinel-to-perovskite transition (also called endothermic phase transition in the literature), the mantle flow is impeded or even arrested because the sinking cold material deflects the boundary downward, resulting in a decrease of the local buoyancy. Latent heat that is adsorbed by the sinking material at the phase transition may partially compensate the boundary deflection and reduce the blocking mechanism. Likewise, upwelling material may be impeded or arrested in a similar manner.

Depending on the pressure gradient within a planet, these transitions are located at different depths. For instance, in the Earth's mantle, the olivine-to-spinel transitions are located at a depth of 400–520 km, whereas in Venus, they occur at 450–580 km, and in the smaller Mars, the depth of this transition zone is roughly between 1000 and 1500 km. Mineral physics experiments and ab initio calculations (Murakami et al., 2004; Oganov and Ono, 2004; Tsuchiya et al., 2004) have indicated that perovskite undergoes an exothermic phase change to a postperovskite structure just above the core–mantle boundary (CMB) of the Earth. For Mercury and the Moon, the pressure gradient is too low, and olivine-to-spinel phase transition pressures are not reached in their mantles. Details of the interior structure of the terrestrial planets and the Moon are given in Chapter 10.02.

10.08.2.2 Heat Sources

The planet's internal heat sources provide the energy for its dynamics, supplying it with the driving energy for mantle convection, and for melting the mantle that may lead to volcanism. The internal heat energy of the terrestrial planets was greater in the early stages of their histories than it is today, having accumulated rapidly by heat conversion associated with three separate processes, all of which were most intense during the first few million years of the planet's history: (1) the accretion of the planet by impacts, (2) core formation and the associated release of gravitational potential energy, and (3) the radioactive decay of unstable isotopes. Another important heat source in a terrestrial body can be tidal dissipation, which may have been important in Earth's early history and will be seen to dominate in the case of Io, later in the text. This heat source is not necessarily higher early in the evolution; rather, it can be highly variable both spatially and temporally and depends on the body's orbital and thermal evolution.

10.08.2.2.1 Accretional heating

Accretion of material during the formation of planets is likely one of the largest sources of heat. The accretional heat is the energy accumulated through the burial of heat by impacts as the planet grows by the accretion of planetesimals. During accretion, a temperature profile is generated for which the temperature increases from the center toward the surface (Figure 1). A possible postaccretional temperature profile assuming homogeneous accretion of the undifferentiated material and ignoring the contribution of short-lived radiogenic elements like ^{26}Al (e.g., Schubert et al., 1986) is given by

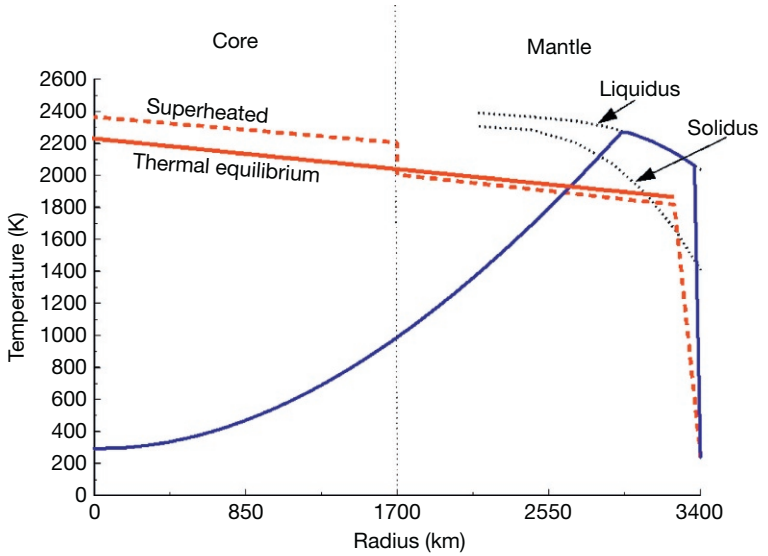

Figure 1 Accretional temperature profile for a planet with the size of Mars (blue solid line) calculated from eqn [1] with a retention factor h of 0.2. The accretional temperature exceeds the solidus and the liquidus close to the surface, thus forming a 600 km deep magma ocean. After core formation, two possible temperature profiles can develop if (1) the core formed in thermal equilibrium with the mantle (solid red line) and (2) the core is superheated with respect to the mantle as the consequence of rapid core formation (dashed red line). The temperature profiles account for the potential energy release due to core formation (eqn [4]). This energy is distributed homogeneously assuming an adiabatic interior.

$$T_a(r) = h\frac{GM(r)}{C_p r}\left(1+\frac{ru^2}{2GM(r)}\right)+T_e+\Delta T_{a,ad} \quad [1]$$

where h is the retention factor describing the contribution of heat retained in the accumulated body, G is the gravitational constant, $M(r)$ is the mass of the planet internal to radius r, C_p is the specific heat, $u^2/2$ is the approach kinetic energy per unit mass, and T_e is the temperature of the surrounding nebula. The postaccretional temperature profile of Schubert et al. (1986) is corrected to account for the temperature rise, $\Delta T_{a,ad}$, caused by adiabatic compression as the internal pressure progressively increases during accumulation.

This accretion temperature distribution is stable against thermal convection and shows an inverse profile, which decreases with depth (**Figure 1**), when compared to a typical temperature profile for planetary interiors, which increases with depth. Depending on the amount of stored heat (part of the energy is radiated back to space) and, in particular, on the size of the body, the accretion profile can rise above the melting temperature of iron and possibly of silicate close to the surface; a magma ocean may form. The temperature distribution due to accretion can also be influenced by predifferentiated planetesimals forming the planet or – if the body formed rapidly enough as suggested for Mars (Dauphas and Pourmand, 2011) – by short-lived radioactive elements such as ^{26}Al. In that case, higher temperatures in the deep interior can be expected.

10.08.2.2.2 Core formation

Planets are assumed to have initially accreted as a mixture of silicate and metal particles. It is, however, likely that some if not all of the planetesimals were already differentiated (e.g., Baker et al., 2005; Kleine et al., 2002) particularly as accretion progresses. The separation of the metal particles, that is, the formation of an iron-rich core, most likely was contemporaneous with or shortly after a planet's accretion. Recent studies on short-lived radionuclides (e.g., ^{182}Hf) suggest that the separation between silicates and iron occurred on the order of $1–5\times10^7$ years after accretion (e.g., Kleine et al., 2002). Estimates of the timescale of the core formation process suggest that for rapid separation, both the silicate and the iron need to be fluid at least in the upper part of the planet (e.g., Stevenson, 1990). In such a scenario, iron accumulates at the base of a magma ocean and sinks further to the center of the planet by Rayleigh–Taylor instability due to iron's larger density. Alternatively, it has been assumed that no global magma ocean formed during accretion; rather, silicate–metal separation takes place without global-scale melting but in magma ponds generated by impacts (Tonks and Melosh, 1992). Numerical studies of this process, however, suggest that the time to form a core would be about 0.5–1 Ga (Senshu et al., 2002) although more recent studies in two- and three-dimensional (2-D and 3-D) show that diapir sinking and thus core formation can be a very fast process (Golabek et al., 2009; Samuel and Tackley, 2008).

The gravitational energy released by core formation is converted into thermal energy through viscous dissipation, which strongly heats the interior. During core formation, when iron sinks to the center, the temperature profile is inverted to decrease from the center toward the surface. The total energy released by the differentiation of a homogeneous planet into an iron-rich core and a silicate mantle can be estimated from the difference between the potential energy stored in a homogeneous planet after accretion, U_H, and the potential energy of the differentiated, two-layer planet, U_D (Schubert et al., 1986). Thus, the energy dissipated by differentiation is

$$U_{Diff} = U_H - U_D \quad [2]$$

with the potential energy stored in a homogeneous body after accretion

$$U_H = -\frac{16}{15}\pi^2 G R_p^5 \rho^2 \quad [3]$$

and with the potential energy of a two-layer planet (with constant density ρ_m in the mantle and ρ_c in the core) given by

$$U_D = -\frac{16}{15}\pi^2 G R^5\left[\rho_m^2+\frac{5}{2}\rho_m(\rho-\rho_m)+\left(\frac{3}{2}\rho_m-\rho_c\right)(\rho_m-\rho_c)\left(\frac{\rho-\rho_m}{\rho_c-\rho_m}\right)^{5/3}\right] \quad [4]$$

If this energy is homogeneously distributed in the planetary interior, that is, if there is thermal equilibrium between the mantle and the core, estimates for the mean temperature increase are about 1000 K for the Earth and about 300 K for Mars (Solomon, 1979). It is, however, likely that due to the assumed rapid core formation process, the core was superheated with respect to the mantle (**Figure 1**). If the core was superheated or not depends strongly on the rheology of the planet and on the segregation mechanisms (Ke and Solomatov, 2009; Samuel and Tackley, 2008).

10.08.2.2.3 Radioactive heat sources

The energy release by accretion and core formation occurred very early in the planet's history since one expects these processes to be very rapid (e.g., Kleine et al., 2002). Thus, they are not responsible for magmatism or tectonics after the first few hundred million years. Instead, long-lived radioactive elements with half-lives of billions of years, primarily ^{238}U, ^{235}U, ^{232}Th, and ^{40}K, become the dominant heat sources. It is this heat that can produce volcanism and power internal convection and tectonics on planets. At present, roughly half of the Earth's heat output is thought to be due to radioactive cooling, while the remainder may be due to secular cooling (loss of sensible heat). For the other terrestrial planets, this ratio (known as the Urey ratio) might be similar. The distribution of the radioactive heat source can change with time as a consequence of chemical differentiation (crustal formation). The radiogenic elements are incompatible in the solid mantle undergoing melting and thus become enriched in the melt. This melt then rises to the surface and forms new crust. If the radioactively enriched crust is stably stratified at the surface, the mantle heat sources are reduced. Short-lived isotopes, in particular ^{26}Al with a half-life of 0.74 Ma, might also have played an important role in heating rocky bodies when the solar system was first forming (e.g., Bizzarro et al., 2004; Lee et al., 1976; MacPherson et al., 1995). The heating rate was high at an early stage but disappeared quickly. Possibly, this strong energy peak was responsible for the differentiation of some of the asteroids (e.g., Ghosh and

McSween, 1998; Merk et al., 2002; Neumann et al., 2012), of planetesimals that formed the planets and early-formed planets (or surviving planetary embryos) such as Mars (Dauphas and Pourmand, 2011).

10.08.2.2.4 Tidal dissipation

An important heat source in terrestrial planets can be tidal energy caused by gravitational interactions between the Sun and the planets and/or between the planets and their satellites. For a satellite that moves on an elliptical orbit, the distance and therefore the gravitational attraction vary periodically. If the interior reacts to this periodic deformation viscoelastically, tidal energy can be dissipated in the form of heat. The heating due to tidal dissipation can, in some cases, exceed the heat released by the decay of radioactive elements. The tidal energy dissipation rate $\dot{E}$ depends on the time variation of the tides, the interior structure, and the rheology (and, hence, temperature) of the dissipating body. Since this energy is derived from the orbital and rotational energies of the interacting bodies, orbital evolution and rotational evolution are therefore coupled to the thermal evolution by the tidal dissipation rate. In the case of a small inclination of the equatorial plane to the orbital plane and a small eccentricity, the tidal dissipation rate in a synchronous satellite can be estimated using the relation by Segatz et al. (1988):

$$\dot{E} \sim \mathrm{Im}(k_2)_{\mathrm{Sat}} \frac{(nR_{\mathrm{Sat}})^5}{G} e^2 \qquad [5]$$

with R_{Sat} the radius of the satellite, n the mean motion, e the eccentricity, $\mathrm{Im}(k_2)_{\mathrm{Sat}}$ the imaginary part of the tidal Love number k_2 (measuring the phase lag of the tide), and G the gravitational constant.

10.08.2.3 Rheology

Rheology is a primary factor affecting convection in terrestrial planets and a rheological prerequisite for convection is that the material behaves on long timescales like a fluid, that is, able to flow under small differential stresses. For mantle rocks, the timescale of deformation is of utmost importance. At high frequency (e.g., the seismic wave band), the mantle is approximately elastic; but at very low frequency (periods larger than 1000 years), the mantle, at sufficient high temperatures and pressure, behaves like a viscous fluid. Unfortunately, such conditions cannot be reproduced in the laboratory and thus the true rheology of planetary mantles is poorly known. What is known is that the viscosity of mantle rocks under the wide variety of conditions in planetary mantles is dependent on temperature, pressure, stress, grain size, and composition (e.g., Karato, 2013).

The exponential dependence of the rheology on the inverse absolute temperature is particularly important in understanding the role of mantle convection in transporting heat. The temperature dependence of the rheology acts as a thermostat to regulate the mantle temperature. Any tendency of the mean temperature to increase is offset by an associated reduction in mantle viscosity, an increase in convective vigor, and a more efficient outward transport of heat. Similarly, a decrease in mantle temperature tends to increase mantle viscosity, reduce convective flow velocities, and decrease the rate of heat transfer. As a result of the sensitive feedback between mantle temperature and rheology, relatively small changes in temperature can produce large changes in heat flux, and the temperature is consequently buffered at the equilibrium point (Tozer, 1965).

The viscosity of the mantle can be written in a simple Arrhenius form as

$$\eta = \eta_0 \exp\left(\frac{A + pV}{RT_{\mathrm{m}}}\right) \qquad [6]$$

In eqn [6], η_0 contains the stress, composition, and grain size-sensitive terms; T_{m} is the mean temperature of the convecting fluid; R is the universal gas constant; A is the activation energy for creep (e.g., Weertman and Weertman, 1975); p is the pressure; and V is the activation volume.

Though planetary mantles are composed of several minerals, olivine is thought to dominate the rheology of silicate mantle rock (e.g., Mackwell, 1991). For dry olivine, the viscosity is about 10^{21} Pa s at a reference temperature of 1600 K (e.g., Karato and Wu, 1993) with an activation energy of about 540 kJ mol^{-1} at pressures of 12 GPa (Karato and Wu, 1993) and an activation volume of about 15 $\mathrm{cm}^3\,\mathrm{mol}^{-1}$ (Karato and Rubie, 1997). This reference viscosity can, for instance, vary with the amount of iron and is a factor of ten lower for the Martian mantle due to its higher iron content in comparison to the Earth's mantle (FeO ~ 17 wt% for Mars vs. FeO ~8 wt% for Mars) (Zhao et al., 2009).

The viscosity is also known to strongly depend on the presence of volatiles. With increasing water content, the viscosity of olivine is reduced by two to three orders of magnitudes in comparison to dry olivine (e.g., Hirth and Kohlstedt, 1996; Mei and Kohlstedt, 2000), resulting in stronger convection for a wet mantle in comparison to a dry mantle at the same temperature and pressure conditions.

10.08.2.4 Thermal Expansivity and Conductivity

The two important parameters for mantle dynamics and thermal evolution of terrestrial planets are the thermal expansivity and the thermal conductivity. The former parameter describes the volume increase per unit temperature increase, that is, the decrease of density with increase of temperature. The thermal conductivity k is a bulk property of material that indicates its ability to conduct heat. In terrestrial mantles, neither parameter is constant although parameterized thermal evolution models often assume a constant value. In various 2-D and 3-D numerical simulations of mantle convection in the Earth and terrestrial planets, the variation of α and k has been examined (e.g., Ghias and Jarvis, 2008; Hansen et al., 1993; Leitch et al., 1991; Matyska and Yuen, 2005; Schmeling et al., 2003; Tan et al., 2011). The thermal expansivity whose magnitude varies among different mineral phases decreases with pressure and increases with temperature (e.g., Chopelas and Böhler, 1989; Katsura et al., 2009a,b; Xu et al., 2004). Chopelas and Böhler (1989) discovered experimentally that for olivine and magnesium oxides, thermal expansivity decreases with the fifth or sixth power of density up to pressures of about 33 GPa. Theoretical estimates of Anderson (1987) suggest a slower

decrease with the third power of density. The temperature dependence of the thermal expansivity results in an increase of α across the top thermal boundary layer below which α decreases again due increasing pressure (e.g., Tosi et al., 2013c). Since the thermal buoyancy force driving convection and the adiabatic cooling are both proportional to the thermal expansivity, one can expect this variation to have an important influence on the convection pattern in planetary mantles (such as Earth, Venus, or larger terrestrial bodies) where the mantle thickness is not much smaller than the density-scale height. The use of a PT-dependent thermal expansivity lengthens the spatial scale of mantle convection – hot plumes are enhanced as they gain buoyancy while rising through the mantle due to an increase of α with decreasing pressure and the descent of cold downwellings is inhibited as they lose buoyancy while sinking due to a decrease of α with increasing pressure (e.g., Hansen et al., 1993; Leitch et al., 1991; Tan et al., 2011; Tosi et al., 2013c).

Thermal conductivity depends on various factors like temperature, pressure, composition, and texture of the material. In the mantle, the phonon contribution, k_{lat}, and the radiative contribution k_{rad} contribute to the thermal conductivity

$$k_{\mathrm{m}}(T,p) = k_{\mathrm{lat}}(T,p) + k_{\mathrm{rad}}(T) \quad [7]$$

The phonon contribution k_{lat} decreases with increasing temperature T and increases with increasing pressure p, whereas the radiative contribution k_{rad} increases with increasing temperature independent of pressure; for relevant temperatures in a terrestrial mantle, the phonon conductivity is much higher than the radiative contribution. As a consequence, a decrease of the thermal conductivity through the upper part of the mantle, that is, the stagnant lid and the upper thermal boundary layer, and an increase through the mantle beneath are expected. Hofmeister (1999) had developed a model for the temperature and pressure dependence of mantle thermal conductivity under terrestrial conditions:

$$k_{\mathrm{lat}}(T,p) = k_{298}\left(\frac{298}{T}\right)^{a}\exp\left[-\left(4\gamma+\frac{1}{3}\right)\alpha(T-298)\right]\left(1+\frac{K_{\mathrm{T}}'p}{K_{\mathrm{T}}}\right) \quad [8]$$

$$k_{\mathrm{rad}}(T) = 0.01753 - 0.00010365T + 2.2451T^2/10^7 - 3.407T^3/10^{11} \quad [9]$$

where k_{298} is the surface thermal conductivity at 298 K, α is the thermal expansivity and is taken to be constant, γ is the Grüneisen parameter, K_{T} is the bulk modulus, and $K_{\mathrm{T}}' = \mathrm{d}K_{\mathrm{T}}/\mathrm{d}P$. The value of a depends on the chemical bonding, with $a = 0.3$ characteristic of silicates and $a = 0.9$ characteristic of oxides. In parameterized convection models, it is often assumed that the thermal conductivity in the terrestrial mantle has a constant value of 4 W m^{-1} K^{-1} (e.g., Breuer and Spohn, 2003; Hauck et al., 2004; Morschhauser et al., 2011; Schubert et al., 1992; Spohn, 1991; Stevenson et al., 1983). Applying eqns [8] and [9] to terrestrial planets, however, shows that the thermal conductivity is typically lower in the upper mantle and higher for a large part of the lower mantle than the assumed value of 4 W m^{-1} K^{-1}. For instance, in Mars, values may range between 2.5 and 3.5 W m^{-1} K^{-1} at the bottom of the upper thermal boundary layer (Schumacher and Breuer, 2006) and are assumed to be $\sim$7 W m^{-1} K^{-1} at the CMB (Keller and Tackley, 2009; Ruedas et al., 2013a,b). For the Earth, values at the CMB range from 6 W mK^{-1} (de Koker, 2010) to about 10 W mK^{-1} (Goncharov et al., 2008; Ohta et al., 2012; Tang and Dong, 2010) to even 20–30 W mK^{-1} (Hofmeister, 2008).

10.08.3 Planform of Convection

Convection is driven by density variations that arise from thermal and chemical variations. Here, we will be primarily concerned with thermal convection. The Rayleigh number describes the degree of instability and the convective vigor of a convecting system. With increasing convective vigor, thermal boundary layers get thinner and the convection planform smaller (Turcotte and Schubert, 1982). Thus, the horizontal scale of instabilities is reflective of the thickness of the layer itself. In general, the scale of convection depends on the geometry of the system, the heating mode, and the mechanical and thermal boundary conditions. For planetary mantles, shear stress-free conditions with an isothermal top boundary are appropriate, while the heating mode can vary from purely basally heated to purely internally heated with any mixed heating mode in between.

Figure 2 shows the critical Rayleigh number (the Rayleigh number at which convection sets in) for bottom-heated (a) and purely internally heated (b) spherical shells, as a function of the aspect ratio of the shell (η = inner radius/outer radius) for different axisymmetric modes of convection, denoted by spherical harmonic degree l (Zebib et al., 1983). As the shell becomes thinner (η increasing), the harmonic degree of the most unstable mode increases, and the critical Rayleigh number for instability decreases, approaching the plane layer values as η approaches 1. Thus, Mercury's mantle with $\eta = 0.75$ has the lowest critical Rayleigh number of all the terrestrial planets. Nonetheless, Mercury's small size leads to a low intrinsic Rayleigh number for the shell and it is not clear if convection occurs at all (e.g., Hauck et al., 2004; Michel et al., 2013; Tosi et al., 2013a).

For small core sizes (low η), the most unstable modes have very low l, and for η below about 0.25, degree-1 mode is the most unstable. This mode has a single, cylindrical upwelling and a broader, weaker downwelling located antipodally. It was thought for some time that this convection mode described the Martian interior, with the huge volcanic upland of Tharsis located above the upwelling. The measurement of the moment of inertia of Mars (Folkner et al., 1997), however, found that the aspect ratio of the Martian mantle is much larger than 0.25, and other solutions for a degree-1 mode were found involving phase transitions (see succeeding text and **Section 10.08.6.4**). Higher-degree modes have more upwellings and downwellings, taking the form of either sheets or columns depending on the polarity of the solution. Sheetlike downwellings seem to be the preferred geometry for planetary mantles, but upwellings may also organize along linear structures (Schubert et al., 2001), perhaps explaining the chains of volcanic highlands such as those seen on Venus (Ratcliff et al., 1997) or the line of large volcanoes in the Tharsis region of Mars.

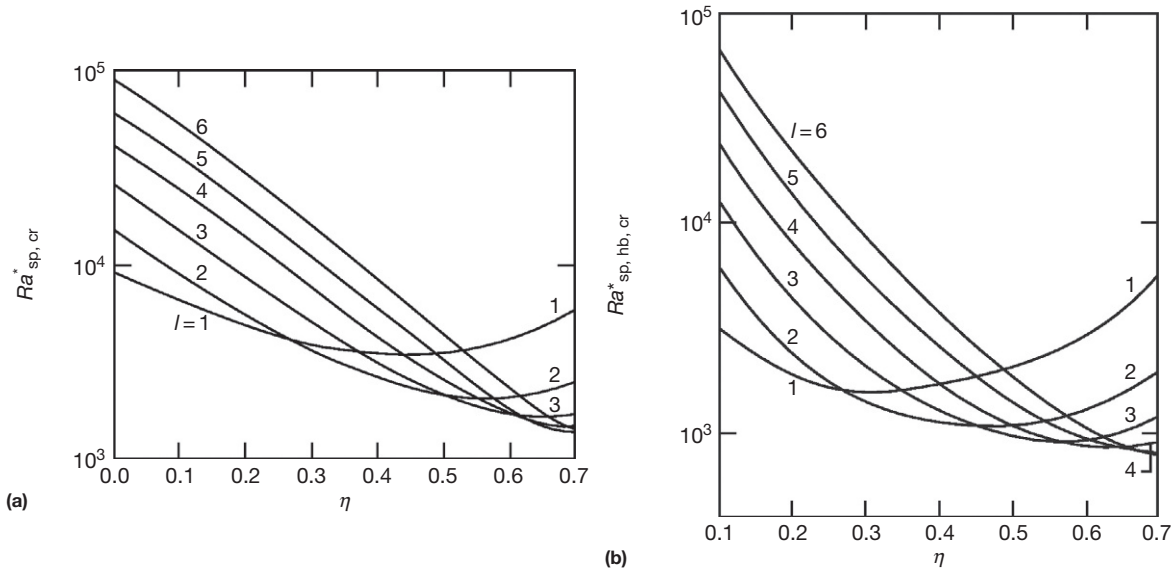

Figure 2 Critical Rayleigh number for bottom-heated (a) and purely internally heated (b) spherical shells, as a function of the aspect ratio η of the shell. The curves for different modes are labeled by spherical harmonic degree l. Reproduced from Zebib A, Schubert G, Dein JL, and Paliwal RC (1983) Character and stability of axisymmetric thermal convection in spheres and spherical shells. *Geophysical and Astrophysical Fluid Dynamics* 23: 1–42. (http://www.informaworld.com).

For a given shell aspect ratio, increasing the Rayleigh number above the critical value causes additional modes to become unstable, some larger-scale (smaller l) and some smaller-scale. As the Rayleigh number continues to increase, more and more high-degree modes become unstable, and the scale of these modes becomes small compared with the depth of the layer. At this point, the cellular nature of the convection breaks down, and the flow is better described by the transient formation of small-scale instabilities in the boundary layers. This happens for Rayleigh numbers of 10^7–10^8, which is close to the values expected for the mantles of Venus and Earth. It has been suggested that the volcanic coronae unique to Venus are the surface expression of such instabilities (Stofan et al., 1991).

Another factor that influences the planform of convection is the presence of mantle phase changes. In Venus and Earth, at least two significant solid-state phase changes associated with the transformation of olivine-to-spinel and spinel-to-perovskite structure are present. The olivine-to-spinel transition is exothermic and has a positive Clapeyron slope and thus can act to enhance convective motions, while the spinel-to-perovskite phase change is endothermic and has a negative slope and thus can act to retard convection (Schubert et al., 1970). The influence of phase changes on convection planform has two aspects: First, if the endothermic phase change can act as a significant barrier to convection, the layer may be split into two independently (or nearly so) convecting layers, each with a higher aspect ratio and a lower Ra than the whole mantle. Second, the effectiveness of the endothermic phase change in resisting convective motions is wavelength-dependent, becoming less effective as the wavelength increases (Bercovici et al., 1993). Thus, this transition can act as a filter, preventing short-wavelength instabilities from passing but allowing larger-scale motions (Tackley, 1996; Tackley et al., 1993, 1994). For Venus, this perhaps explains the large-scale structure of the highland regions superimposed on the small-scale features that generate the coronae. In Mars, the olivine-to-spinel transition falls near the middle of the mantle, but the spinel-to-perovskite transition, if it is reached at all, is located very near the core. Convection calculations with this geometry show that the number of upwellings originating from the CMB is reduced by the presence of the endothermic phase transition and that single-plume planforms are possible (Harder, 1998; Harder and Christensen, 1996).

Convection planform is also influenced by rheological stratification. Although we know very little of the interior structure of the other terrestrial planets, the Earth shows a strong rheological contrast between the upper mantle and lower mantle, with estimates ranging from a factor of 30 to 1000 in the viscosity difference between the upper mantle and lower mantle (e.g., Cadek and Fleitout, 2003; Hager and Richards, 1989; Kaufmann and Lambeck, 2000; Peltier and Jiang, 1996). Additionally, the viscosity of mantle materials shows a continuous increase with pressure. Finally, the Earth exhibits a global or nearly global low-viscosity zone (asthenosphere) beneath the lithosphere. The rheological stratification of the Earth affects the length scales of convection in two ways: First, the high-viscosity lower mantle has an effective Rayleigh number that is lower than the mantle as a whole, and thus, the scale of instabilities will increase relative to the upper mantle. Second, the low-viscosity zone acts to decrease the dissipation associated with shear across the upper thermal boundary layer, allowing longer cells to form (Busse et al., 2006; Lenardic et al., 2006). It is not clear if either of these effects is present in the other terrestrial planets. The low-viscosity zone, in particular, is thought to be related to the recycling of water into the mantle by subduction, a process that is at present not relevant to the other bodies.

10.08.4 Thermal Evolution Models Using Parameterized Convection

Thermal evolution calculations with 2-D or 3-D mantle convection codes are very time-consuming on present-day computers. In these calculations, a set of differential equations have to be solved for the conservation of mass, momentum, and energy including an appropriate constitutive equation. Because of the inherent complexity in these models, it is often desirable to take an empirical approach and parameterize the convective heat transfer rate as a function of known quantities. Such parameterizations can be derived using simple theories, which result in scaling laws that describe the heat transport in the interior as a function of the convective parameters.

Our improving understanding of the heat transport mechanisms on terrestrial planets over the last two decades has led to repeated changes in the preferred scaling law used to model the thermal evolution of one-plate planets. Initially, the scaling law for a fluid with constant viscosity was used for one-plate planets. In the meantime, it has been recognized that this scaling law models the heat transport in a planet where convection comprises the whole mantle including the outer layers. In fact, such a model describes the heat transport in a planet with plate tectonics better than that in a one-plate planet (e.g., Schubert et al., 2001). The plate tectonic regime is expected to cool the planet very efficiently because the comparatively cold outer layers become recycled into the interior of the mantle by convection (Figure 3).

Subsequent attempts to model the heat transport in one-plate planets included the effects of a growing lithosphere in the models with parameterizations based on constant viscosity scaling laws (e.g., Schubert et al., 1990). The base of the non-convecting lithosphere is represented by an isotherm characteristic of the transition from viscous deformation to rigid response to loads applied over geologic timescales (e.g., Schubert et al., 1992). Such a model represents the heat transport in a planet with a single plate on top of a convecting mantle. However, this model assumes that the lid coincides with the rheological lithosphere, that is, the region of the planet's crust and mantle over which the flow properties of rock are insufficient to relieve stress. The part of the upper mantle that is weaker than the rheological lithosphere is assumed to be constantly recycled within the mantle. In comparison to the recently derived stagnant lid parameterization, these models, therefore, represent a mechanism of lithosphere delamination. The efficiency of the heat transport by lithosphere delamination is in between that of plate tectonics and that of stagnant lid convection.

More recently, new scaling laws have been derived from convection models in layers of fluids with strongly temperature-dependent viscosities (e.g., Davaille and Jaupart, 1993; Deschamps and Sotin, 2000; Grasset and Parmentier, 1998; Hüttig and Breuer, 2011; Moresi and Solomatov, 1995; Reese et al., 1999; Richter, 1978; Solomatov, 1995; Solomatov and Moresi, 2000). These scaling laws have been suggested to represent the heat transport in a planet with a single plate on top of a convecting mantle. This stagnant lid convection predominantly cools the outer layers of a planet through stagnant lid growth while the deep interior is cooled rather inefficiently.

In the following, various approaches to model the heat transport that are based on either constant (Section 10.08.4.1) or temperature-dependent (Section 10.08.4.2) viscosity fluids will be introduced.

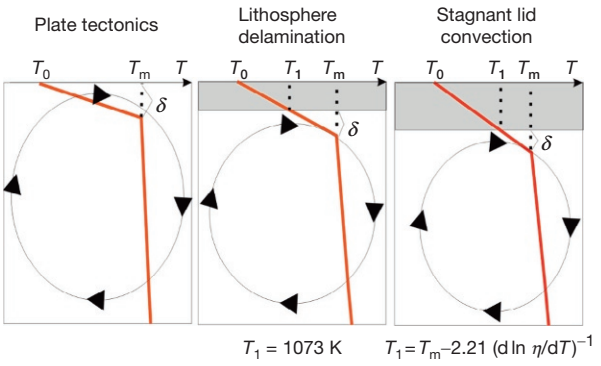

Figure 3 Sketch of the convective flow (circle with arrows) and the temperature profiles (red lines) in a mantle for three different heat transport mechanisms. In the plate tectonic regime, mantle convection comprises the entire mantle including the outer layers. For this regime, the temperature difference across the thermal boundary layer (δ), which drives the convection, is given by $T_m - T_0$ (with T_m the interior temperature of the convecting mantle below the thermal boundary layer and T_0 the surface temperature). In the stagnant lid model and the lithosphere delamination model, mantle convection occurs below a lid (shaded area). The temperature difference across the thermal boundary layer is given by $T_m - T_l$ (with T_l the temperature at the base of the lid). T_l differs between these two models, being constant for the lithosphere delamination model and dependent on T_m and the mantle rheology for the stagnant lid model.

10.08.4.1 Parameterizations Based on Constant Viscosity Laws

From convection experiments and boundary layer theory for constant viscosity fluids, the classical power law relationship between heat flow and convective parameters (e.g., Roberts, 1979; Turcotte and Oxburgh, 1967) has been derived:

$$Nu = aRa^{\beta} \qquad [10]$$

This equation relates the dimensionless heat flux out of the convecting layer, expressed as the Nusselt number, Nu, to the strength of thermal convection as measured by the Rayleigh number, Ra. The parameters a and β are constants, with a typically ranging between 0.195 and 0.339 and β between 1/4 and 1/3 depending on the geometry of the convecting layer, the heating mode, and the boundary conditions (e.g., Deschamps and Sotin, 2000; Deschamps et al., 2010; Jarvis, 1984; Ratcliff et al., 1996; Schubert and Anderson, 1985; Sotin and Labrosse, 1999; Wolstencroft et al., 2009; Yanagisawa and Yamagishi, 2005; Zebib et al., 1985; Zhong, 2005).

The Nusselt number is a measure of the ability of convection to transfer heat in comparison with thermal conduction. It is calculated by dividing the average surface heat flux, q_s, by the theoretical conductive heat flux, $k\Delta T_d/d$, where d is the

thickness of a conductive fluid layer, k is the thermal conductivity, and ΔT_d is the temperature jump across the fluid layer:

$$Nu = q_s \frac{d}{k\Delta T_d} \quad [11]$$

For convection, the surface heat flow is given by

$$q_s = k\frac{\Delta T_\delta}{\delta} \quad [12]$$

where δ is the thickness of the upper thermal boundary layer and ΔT_δ is the temperature difference across this boundary layer. With convection, Nu is larger than one. The Rayleigh number is defined as

$$Ra = \frac{\alpha\rho g\Delta T_d d^3}{\kappa\eta} \quad [13]$$

where α is the thermal expansivity, ρ is the density, κ is the thermal diffusivity, g is the acceleration due to gravity, and η is the viscosity of the fluid.

The power law in eqn [10] has been applied to model the thermal evolution not only of terrestrial planets, for example, of the Earth with a plate tectonic regime, but also of one-plate planets such as Mercury, Venus, and Mars (e.g., Schubert, 1979; Schubert et al., 1979a; Sharpe and Peltier, 1978; Stevenson et al., 1983). Equation [10] has been used although the viscosity η of the terrestrial mantles is thought to be strongly temperature-dependent (eqn [6]).

The models for one-plate planets have later been modified to include the effects of a growing lithosphere by Spohn and Schubert (1983) (see also Schubert et al., 1992; Spohn, 1991) using an equation for the growth of a lithosphere, which was first proposed by Schubert et al. (1979b):

$$q_m - q_l = \rho_m C_m (T_m - T_l)\frac{dl}{dt} \quad [14]$$

where q_m and q_l denote the heat flow into the lithosphere from the convecting mantle and the heat flow through the lithosphere by conduction, respectively; C_m is the heat capacity; T_l is the temperature at the base of the lithosphere; T_m is the temperature in the mantle at the base of the upper thermal boundary layer; l is the thickness of the lithosphere; and t is the time. The base of the lithosphere in these models is an isotherm assumed to be characteristic for the transition from viscous deformation to rigid response to loads applied over geologic timescales. This lithosphere can be identified with a rheological lithosphere. A representative value of T_l is around 1073 K.

10.08.4.2 Stagnant Lid Parameterization Based on Temperature-Dependent Viscosity Laws

In recent years, experimental and numerical studies (e.g., Davaille and Jaupart, 1993; Deschamps and Sotin, 2000; Grasset and Parmentier, 1998; Hüttig and Breuer, 2011; Moresi and Solomatov, 1995; Richter, 1978; Reese et al., 1998; Reese et al., 1999; Solomatov, 1995; Solomatov and Moresi, 2000) have improved our understanding of convection in layers of fluids with strongly temperature-dependent viscosities. It has been shown that the simple scaling law (eqn [10]) is only applicable if the viscosity ratio across the layer is relatively small.

Three basic regimes of convection are found to occur, depending on the variation in viscosity between the hot interior of the convecting fluid and the cold surface: the small-viscosity regime, the transitional regime, and the stagnant lid regime. If the viscosity ratio across the layer is relatively small (smaller than about 100), the cold thermal boundary layer is mechanically similar to the rest of the fluid, and the convection planform and the temperature distribution are essentially the same as in constant viscosity convection. For larger viscosity ratios (between about 100 and several thousand), the cold thermal boundary layer participates in the convection but deforms more slowly than the interior of the convecting fluid and thereby controls the heat transfer (transitional regime). With a viscosity ratio greater than about 10^4, a so-called stagnant lid will form on top of the underlying convecting layer. This critical viscosity ratio also depends on the increase of the viscosity with depth (Hüttig and Breuer, 2011). This stagnant lid (**Figure 3**) is not participating in the convective flow and most of the viscosity variation is within the lid.

Convection in the layer below the stagnant lid is driven by the nonadiabatic temperature difference across it. The viscosity variation in this convecting layer is small, that is, by only about one order of magnitude. Numerous studies assuming heating from below (e.g., Moresi and Solomatov, 1995; Morris and Canright, 1984; Solomatov, 1995) or assuming heating from within (e.g., Choblet and Sotin, 2000; Grasset and Parmentier, 1998; Hüttig and Breuer, 2011; Solomatov and Moresi, 2000) find a viscosity ratio in the convecting layer smaller than 10. This observation is also independent of the assumed mantle rheology law, whether or not it is linear (Newtonian) or a power law (non-Newtonian).

All terrestrial planets other than the Earth presently show a stagnant lid on their surface. For such a lid to form, the following condition is required (Solomatov, 1995):

$$\theta \equiv \frac{d\ln\eta}{dT}\Delta T > \ln 10 \quad [15]$$

For commonly assumed mantle rheology parameters, including the activation energy with $A \sim 400$ kJ mol^{-1} (e.g., Turcotte, 1982), and typical deep mantle temperatures of terrestrial planets (i.e., between about 1600 and 2500 K), the parameter θ is much larger than 10, which would imply that all terrestrial planets would be in the stagnant lid regime. A problem with the stagnant lid model, however, is that it may be ignoring some important aspects of mantle convection since the Earth also meets the previously mentioned criterion for stagnant lid convection but instead has plate tectonics. For plate tectonics to occur, more complex rheologies need to be considered that mimic, for instance, distributed brittle deformation (e.g., Bercovici, 2003; Höink et al., 2012; Moresi and Solomatov, 1998; Tackley, 2000; Trompert and Hansen, 1989) because simple temperature-dependent rheologies lack the modes of deformation responsible for the lithosphere strain localization and weakening responsible for plate boundary formation. Of course, such deformation mechanisms must be plausibly inoperative or ineffective on the other terrestrial planets lacking plate tectonics.

Davaille and Jaupart (1993) had shown with their experiments on internally heated fluids that the temperature at the base of the stagnant lid, T_l, can be expressed as a function of the temperature of the underlying convecting layer, T_m, measured just below the thermal boundary layer, and the rate of change of viscosity with temperature:

$$T_l = T_m - 2.21\left(\frac{d\ln\eta}{dT}\right)^{-1} \quad [16]$$

Assuming a mantle viscosity as described by eqn [6] without pressure dependence, for stagnant lid convection, the temperature difference across the upper thermal boundary layer that drives the convection of the fluid (see Figure 3), if heated from within, is

$$\Delta T_{SL} = T_m - T_l = 2.21\frac{RT_m^2}{A} \quad [17]$$

A similar relation has been obtained from numerical experiments by Grasset and Parmentier (1998) also with internally heated fluids. Choosing representative parameter values for a terrestrial mantle with $T_m \sim 1800$ K and $A \sim 400$ kJ mol^{-1}, the difference between T_m and T_l is small, of the order of 100 K. This temperature difference across the thermal boundary layer is small in comparison to $(T_m - T_l)$ in earlier models based on constant viscosity laws. In these models, T_l equals the surface temperature and $T_m - T_l$ is about 1200 K or, if a rheological lithosphere is considered, T_l is about 1073 K (e.g., Schubert et al., 1979b). In that case, $T_m - T_l$ is about 700 K. Thus, the stagnant lid comprises the rheological lithosphere and is likely to be much thicker than the latter. As a consequence of the relatively high temperatures at the base of the stagnant lid, material in the lower part of the lid may have comparatively low viscosities and may be easily deformable on geologic timescales.

In the present literature, there are at least two different approaches to parameterize the heat transport through a strongly temperature-dependent fluid in the stagnant lid regime. These two approaches differ in the time-dependent versus quasi-equilibrium treatment of the stagnant lid and are otherwise equivalent:

1. The approach by Grasset and Parmentier (1998) is based on the following rules for the stagnant lid regime: The interior of a layer adjusts so that the viscosity contrast across the convective thermal boundary layers is about 10. In the convecting layer, the scaling law for a fluid with constant viscosity is valid, and the Nusselt–Rayleigh number relationship for a fluid with constant viscosity is used (eqn [10]). The thickness of the stagnant lid is determined by equating the heat flux through the lid to the heat flux from the underlying convecting layer into the lid, according to eqn [14]. Instead of using an isotherm at the base of the stagnant lid, the temperature is time-dependent and calculated from eqn [16]. The conductive heat transfer rate within the stagnant lid is calculated from a time-dependent heat conduction equation.
2. In the second approach (e.g., Moresi and Solomatov, 1995; Reese et al., 1999; Solomatov, 1995; Solomatov and Moresi, 2000), a scaling law is derived for the whole layer, that is, the convecting part of the layer and the stagnant lid:

$$Nu = a\theta^c Ra_i^\beta \quad [18]$$

The constants a, c, and β vary with the properties of the convective regime. The internal Rayleigh number, Ra_i, is based on the total temperature drop across the layer and on the viscosity evaluated at the temperature of the interior below the stagnant lid and the upper thermal boundary layer. In addition to the internal Rayleigh number, a second parameter is introduced for this approach, the Frank–Kamenetskii parameter, θ, which is the natural logarithm of the viscosity contrast across the convecting layer (eqn [15]).

10.08.4.3 Plate Tectonics, Lithosphere Delamination, and Stagnant Lid Convection

The parameterizations based on constant and temperature-dependent viscosity laws introduced in Sections 10.08.4.1 and 10.08.4.2 are used to describe the heat transport mechanisms in a terrestrial planet by either plate tectonics, lithosphere delamination, or stagnant lid convection (Figures 3 and 4). In the following, we use for all model calculations parameters that correspond to the planet Mars (see Table 1).

To calculate the thermal evolution, the energy balance of the mantle and the core has been solved:

$$\rho_m C_m V_m \frac{dT_m}{dt} = -q_m A_m + q_c A_c + Q_m V_m \quad [19]$$

$$\rho_c C_c V_c \frac{dT_c}{dt} = -q_c A_c \quad [20]$$

where V_m and V_c are the volume of the convecting mantle and the core; A_m and A_c are the surface area of the mantle and the core; T_m and T_c are the temperature of the isothermal mantle below the conductive layer and the temperature of the core, respectively; q_m and q_c are the heat flow out of the mantle and the core; and Q_m is the heat production rate in the mantle

$$Q_m = Q_0 \exp(-\lambda t) \quad [21]$$

where Q_0 is the initial heat generation rate, λ is the decay constant, and t is the time.

The heat flow of the mantle and the core is calculated from eqn [12] with δ the thickness of the upper or lower thermal boundary layer and ΔT_δ the temperature difference across the upper or lower boundary layer. The thickness of the boundary layers is calculated from eqn [13] replacing d with δ and assuming that the layers become unstable when Ra reaches a critical value, Ra_{crit}. The lid of the stagnant lid and the lithosphere delamination model grow in thickness with time according to eqn [14].

Stagnant lid parameterization models show that the lid will thicken rapidly as the planet cools, while the temperature of the underlying convecting mantle and core will change comparatively little (Figure 4(a)–4(c)). With plate tectonics, there

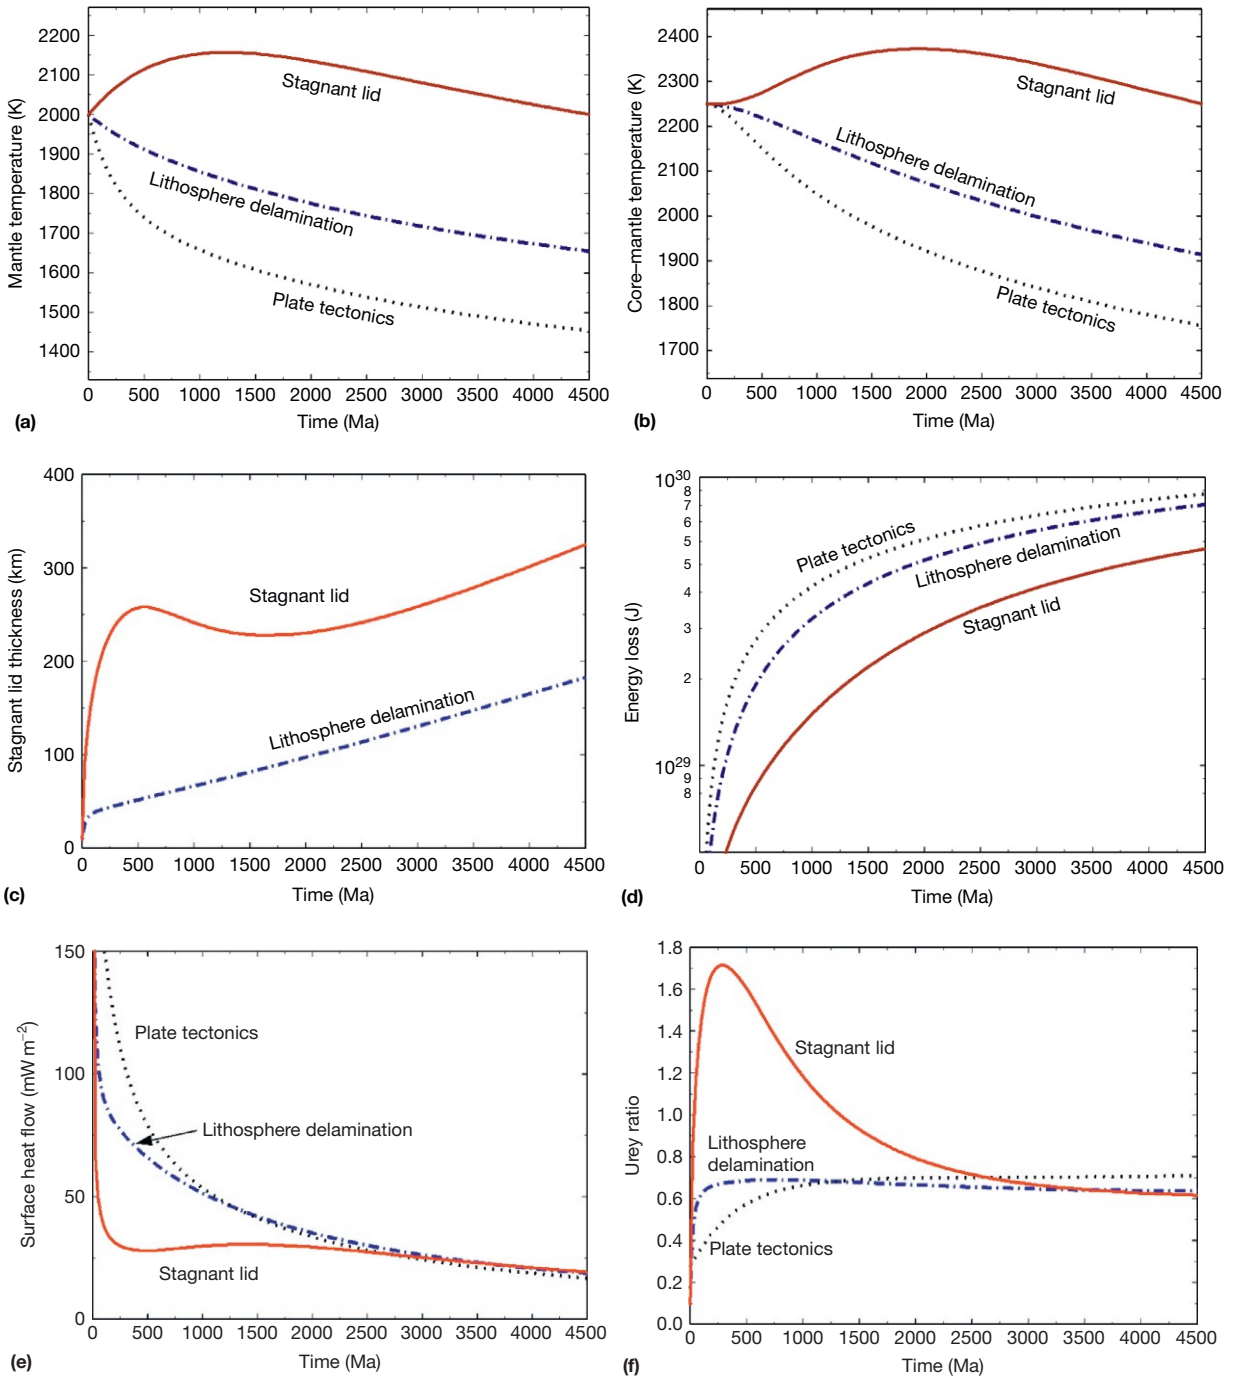

Figure 4 Mantle temperature (a), core–mantle temperature (b), stagnant lid thickness (c), energy loss (d), surface heat flow (e), and Urey ratio (f) as a function of time for three different heat transfer models: stagnant lid convection (red line), lithosphere delamination (dash-dotted blue line), and plate tectonics (dotted line). For further description, see text.

is, of course, no growth of a lid and the cooling of the deep interior is most efficient. The evolution of the lid thickness and the mantle temperature for the lithosphere delamination model is in between the two extremes. For the stagnant lid model, the conductive layer grows rapidly during the first few hundred million years and its thickness varies comparatively little thereafter. Plate tectonics and lithosphere delamination models show an approximately constant rate of increase in the conductive layer thickness. Although the present-day thickness of the stagnant lid differs significantly among the models (320 km for the stagnant lid model, 180 km for the lithosphere delamination model, and no lid for the plate tectonic model), the present-day thickness of the conductive layer is relatively similar for all three models.

Table 1 Definition of parameters and their values for the thermal evolution models in **Section 10.08.4.3**

Parameter	*Notation*	*Value*	*Unit*
Radius of the planet	R_p	3400×10^3	m
Radius of the core	R_c	1700×10^3	m
Gravity	g	3.7	$m\ s^{-2}$
Density of the mantle	ρ_m	3500	$kg\ m^{-3}$
Heat capacity of the mantle	C_m	1000	$J\ kg^{-1}\ K^{-1}$
Mantle thermal expansivity	α	2×10^{-5}	K^{-1}
Mantle thermal diffusivity	κ	10^{-6}	$m^2\ s^{-1}$
Mantle thermal conductivity	k	4	$W\ m^{-1}\ K^{-1}$
Surface temperature	T_0	220	K
Gas constant	R	8.3144	$J\ mol^{-1}\ K^{-1}$
Initial heat source density	Q_0	1.6×10^{-8}	$W\ m^{-3}$
Decay constant	λ	10^{-17}	s^{-1}
Exponent of the Nu–Ra relation	β	1/3	
Critical Rayleigh number	Ra_{crit}	450	

Figure 4(d) and 4(e) compares the cumulative energy loss, that is, the energy loss over the entire evolution of the planet and the surface heat flow of the three models with $A = 300\ kJ\ mol^{-1}$. Stagnant lid convection cools the entire planet least effectively. After 4.5 Ga, the energy loss is about 3.1×10^{29} J smaller for the stagnant lid model compared to the plate tectonic model and 2.3×10^{29} J smaller for the stagnant lid model compared to the lithosphere delamination model. Such energy losses, when distributed homogeneously over the entire mantle, imply that the present-day mantle is about 600 K cooler in the plate tectonic model and about 450 K cooler in the lithosphere delamination model than it is in the stagnant lid model.

It may be speculated that a planet, in which heat is transported effectively by plate tectonics, has a higher surface heat flow than a planet in the stagnant lid regime. However, this is only true in the early part of its evolution. After about 2.5 Ga, the surface heat flow becomes slightly higher in the stagnant lid model. The albeit small difference in the present-day surface heat flow has also implications for the Urey ratio, that is, the ratio of the heat produced within the mantle by radioactive decay to the total surface heat flow (Figure 4(f)). The present-day Urey ratio for our Mars-like test planet is about 0.6 for the stagnant lid regime and 0.7 with plate tectonics. For the lithosphere delamination model, the present-day value is in between the two models of stagnant lid convection and plate tectonics. The contribution of secular cooling at present is, therefore, slightly higher for a planet in the stagnant lid regime than for a planet with plate tectonics assuming the same mantle parameters.

A strong decrease of the surface heat flow can be observed during the first 250 Ma for the stagnant lid model. The strong decrease in the surface heat flow is caused by the adjustment of the lithosphere, which grows rapidly from 10 to 250 km as a consequence of the inefficient heat flow out of the convecting mantle and the more efficient heat transport through the conductive layer. The thicker the assumed initial lithosphere and the lower the initial mantle temperatures, the slower is the decrease of the surface heat flow in the early evolution. The cooling behavior during the early stage of the planet's evolution is, therefore, strongly dependent on the initial conditions. It has been argued by Choblet and Sotin (2000) that an initial stage up to 1 Ga cannot be described by the stagnant lid parameterization, which is based on steady-state convection models. During that initial transitional stage, the mantle cools by conduction until the upper thermal boundary layer becomes unstable due to increased mantle temperatures and reduced viscosities, and convection sets in. The length of this initial stage depends strongly on the early temperature distribution, that is, the hotter the early planet, the shorter is this transitional phase (Choblet and Sotin, 2000). As in general a high interior temperature up the melting temperature in the upper mantle is suggested for terrestrial planets (see **Section 10.08.2.2**), the stagnant lid parameterization can be applied after a few tens to hundred million years after planet formation.

10.08.5 Thermal Evolution, Volcanic History, and Magnetic Field History of Terrestrial Planets

The various parameterized approaches, described earlier in the text, have been used to calculate the thermal histories of the terrestrial planets and a significant amount of work has been published to date (e.g., Breuer and Spohn, 2003; Fraeman and Korenaga, 2010; Grott et al., 2011a,b; Hauck and Phillips, 2002; Morschhauser et al., 2011; Schubert, 1979; Schubert et al., 1979a, 1990, 1992; Sharpe and Peltier, 1978; Spohn, 1991; Stevenson et al., 1983). According to these previous models, the terrestrial planets are differentiated rapidly into a solid mantle and a fluid core (see also **Sections 10.08.2.2.1** and **10.08.2.2.2**). The temperature distribution subsequent to core formation, therefore, serves as the initial boundary condition for the thermal evolution models. Early thermal evolution models use fixed initial temperatures (e.g., Breuer et al., 1993; Schubert and Spohn, 1990; Schubert et al., 1992; Spohn, 1991). The main reason not to vary the initial temperature distribution, which is basically unknown, can be justified by a characteristic feature of the thermal evolution models: The strong temperature dependence of mantle viscosity acts as a thermostat regulating the average mantle temperature (Tozer, 1965). For a hot planet, mantle viscosity is low, and extremely vigorous convection rapidly cools the planet. For a relatively cool planet, the mantle viscosity is higher, and more moderate convection cools the planet at a reduced rate. Self-regulation tends to quickly bring the viscosity of the mantle to a value that facilitates efficient removal by convection of the heat generated in the mantle. Even an initially cold mantle would heat up by radioactivity until the self-regulated viscosity is reached. As a consequence of the self-regulation, the present state of the convecting mantle has little or no memory of the initial conditions. This circumstance makes the early thermal evolution models more applicable, in particular because the initial state is unknown. However, if one is interested in crustal growth, atmosphere evolution, and magnetic field generation of a planet, in particular in its early evolution, knowledge about the early temperature distribution is required

(e.g., Breuer and Spohn, 2003, 2006; Fraeman and Korenaga, 2010; Grott et al., 2011a,b; Hauck and Phillips, 2002; Morschhauser et al., 2011).

Crustal growth and dynamo action in the core are strongly coupled with the thermal evolution of a planet since both processes depend on the vigor and the mode of convection in the mantle. A model of a planet's evolution and tectonics is therefore required to explain the evolution of the magnetic field, and it must also account for the formation of the core of the planet and for the formation and growth of its crust. Furthermore, the thickness of the elastic lithosphere places important constraints on the thermal evolution of a planet. The elastic lithosphere is the upper layer of a terrestrial planet that supports stresses over geologically long ($\sim 10^8$ a) intervals and its thickness can be derived by a joint analysis of the gravity and topography data or from flexural modeling to match the topography (see **Chapter 10.05**). Since the base of the elastic (mechanical) lithosphere can be defined by an isotherm that depends on the rheology (composition) and the strain rate (McNutt, 1984), its thickness allows rough estimates of the surface heat flow. It is important to note that the elastic lithosphere thickness obtained by gravity and topography data does not represent the current state of the thermal lithosphere. It rather shows the thermal state at the time of formation of the considered geologic structure. Thus, the elastic lithosphere thickness provides constraints on models of thermal evolution.

For a typical terrestrial mantle material dominated by olivine, this isotherm can be estimated to be about 1050 K using the rheology parameters of Karato et al. (1986) and a strain rate of 10^{-17} s^{-1}. This isotherm defines the maximum thickness of the elastic lithosphere since the thickness of the effective elastic lithosphere decreases with its deflection. Furthermore, the crust can significantly reduce the elastic thickness since the crust is intrinsically weaker than the mantle (e.g., Burov and Diament, 1995).

10.08.5.1 Crustal Formation

The crust of a terrestrial planet forms when partial melt of the mantle rises toward the surface. Thus, the composition, the thickness, and the time of emplacement of the crust can give us important constraints on the thermochemical evolution; it tells us about the interior temperature distribution and how the processes forming the crust vary with time. On the other hand, the crust itself influences the thermal evolution. (1) Melt that forms the crust is enriched in radioactive elements and in volatiles such as water and CO_2. The consequence is the redistribution of the radioactive elements and the volatiles and in particular a depletion of the mantle in these elements. (2) Crustal material has a different composition and structure than mantle material. The consequence is a lower thermal conductivity of the crust in comparison to the conductivity of the mantle, thus a less efficient heat transport through the outer layer.

10.08.5.1.1 Primary and secondary crustal formation

The process of crustal formation on terrestrial planets can, in general, be divided into two phases: primary crustal formation and secondary crustal formation. A primary crust can be formed as a consequence of efficient differentiation due to core formation and/or freezing of a magma ocean. Such a primordial crust can be strongly enriched in radioactive elements as suggested for the anorthositic crust on the Moon and may have strongly depleted the mantle (for reviews, see Warren, 1985, and Elkins-Tanton, 2012). Except for the Moon, the existence, persistence, and composition of such a crust for the terrestrial planets are however unknown.

The presence of an early magma ocean on a terrestrial planet suggests chemical stratification of the mantle due to fractional crystallization. Fractional crystallization of a cooling magma ocean is generally accepted as an explanation of the observed dichotomy between the Eu-enriched anorthositic crust and the Eu-depleted basaltic source regions of the Moon (e.g., Wood et al., 1970). Assuming the magma ocean freezes rapidly during about 100–200 Ma (e.g., Elkins-Tanton et al., 2003, 2005; Minear and Fletcher, 1978; Solomon and Longhi, 1977) without any disturbances, this part of the mantle most likely became chemically stratified following magma ocean differentiation and crystallization with the late dense iron-rich phases coming to rest upon a less dense Mg-rich phase. Furthermore, most of the incompatible and heat-producing elements would have been enriched in the residual melt forming the so-called KREEP-rich (standing for potassium, rare earth elements, and phosphorus) layer and leaving the mantle of the original magma ocean strongly depleted in radioactive heat sources. In case of the Moon, this layer is located just below the anorthositic (plagioclase-rich) crust that formed through flotation of the low-density plagioclase to the top of the magma ocean. On larger planets such as Mars and the Earth, plagioclase does not become stable due to the higher-pressure gradient until the magma ocean has solidified to a high degree close to the planetary surface, where high crystal fractions also prevent flotation. Furthermore, water in silicate melts suppresses plagioclase (e.g., Goldsmith, 1982). Thus, for large and wet planets assuming a global and fractional crystallizing magma ocean, a dense crust highly enriched in iron-rich phases and radioactive elements is more likely (Elkins-Tanton et al., 2003).

Chemical fractionation, which results in mantle layers of different compositions and densities, strongly influences the subsequent thermochemical evolution of the planet (e.g., Elkins-Tanton et al., 2003; Hess and Parmentier, 1995). The unstable layering due to fractional crystallization (dense cumulate material on top of a less dense material below) may result in a global overturn of the crustal and mantle material. However, for the larger terrestrial planets like Earth and Venus, and possibly for Mars, Tonks and Melosh (1990) argued that the higher-pressure gradient for those planets as compared to the Moon and Mercury inhibits efficient chemical fractionation. The magma ocean rather would have started to cool via equilibrium crystallization (Solomatov and Stevenson, 1993). The existence of a magma ocean in general has been questioned from numerical modeling of a growing Mars (Senshu et al., 2002). The models show no global magma ocean formed during accretion; instead, small magma ponds form by the impacts – these models, however, neglect, for instance, the efficient heating by short-lived radioactive isotopes and assume that Mars formed only from small planetesimals.

In the subsequent evolution after freezing of the magma ocean, a secondary crust that is usually basaltic is formed by

partial melting of the mantle. Depending on the degree of early mantle differentiation, the entire mantle (or only part of the upper mantle) is already depleted in crust-forming material. The formation of the secondary crust depletes the mantle further in radioactive elements as those are incompatible and enriched in the melt that form the crust. The mechanisms of crustal formation differ between a plate tectonics and a one-plate planet.

Plate tectonics provides for crustal formation in a two-step fashion (see Condie (1997) for a discussion of plate tectonics and the Earth's crust and Schubert et al. (2001) for a discussion of plate tectonics and mantle convection). Crustal formation is most effective at divergent plate boundaries, where rising hot mantle material crosses the solidus near the surface. This pressure-release melting generates basaltic crust that is continuously recycled at convergent plate boundaries. More silicic crust is produced in a second differentiation step at convergent plate boundaries where basaltic crust is remelted (together with continental sediments and possibly mantle rock) to form new continental-like crust. Efficient crustal recycling – in particular of the oceanic crust – occurs at the subduction zones at plate margins.

For one-plate planets, there is no two-stage differentiation. Instead, melt is formed underneath the lithosphere usually at greater depth than with plate tectonics. The crust produced is assumed to be basaltic. In contrast to crustal formation at the divergent plate boundaries on plate tectonic planets, crustal growth is limited by the increasing thickness of the lithosphere as the planet cools. First, because buoyancy of the melt decreases with increasing depth to the source region, the melt is more compressible than the mantle rock. Second, the melt needs to rise through the ductile lower and the upper elastic parts of the lithosphere. For the latter, the permeability of the elastic part of the lithosphere to magma ascent decreases with increasing thickness and pressure. Nonetheless, volcanism is observed even on a body with a thick crust and weak gravity such as the Moon. Crustal recycling is not efficient in one-plate planets and is associated with crustal delamination that requires the lowermost crust to undergo mineral equilibration under eclogite facies. The lower crustal layer then becomes denser that the underlying mantle (e.g., Arndt and Goldstein, 1989) and is able to sink into the interior. The basalt–eclogite transition occurs for Earth at a pressure of about ~1.2 GPa (45 km on Earth and 50 km on Venus) and a temperature higher than ~850 K. A different composition further influences the occurrence of the transition. For example, the basalt–eclogite transition on Mars would occur at a lower pressure than for the Earth, due to its iron-rich composition (Babeyko and Zharkov, 2000). Secondary crustal formation may also result in a chemical layering of the mantle as suggested for the primary crust that forms from freezing of a magma ocean. When basaltic melt is extracted from the mantle and segregates to form the surface layer, fertile mantle rock reduces to harzburgite. Under certain melting conditions (Schutt and Lesher, 2006), harzburgite is less dense than its fertile source rock, and this layer can have a stabilizing effect on the mantle dynamics and prevent further cooling of the planet. Depending on the thickness of the depleted layer (e.g., Fraeman and Korenaga, 2010; Ogawa and Yanagisawa, 2011; Plesa and Breuer, 2014; Ruedas et al., 2013a; Schott et al., 2001), three different evolution scenarios are possible: (1) The layer is located in and thinner than the stagnant lid and thus has no influence on the thermal evolution of the planet. (2) The harzburgite layer grows faster than the stagnant lid, further slowing the cooling of the planet as the thickness of the nonconvecting part of the mantle increases and inefficiently transports heat by conduction. (3) The harzburgite layer is sufficiently thick that it can convect separately from the lower fertile mantle. Such two-layer convection results in inefficient cooling of the deep interior. The thickness and the evolution of the depleted harzburgite layer depend on the mantle composition associated with the density difference between primordial mantle and depleted mantle, on the mantle temperature, and especially on the depth of melting, that is, for high temperature, the melting is deeper, and the depleted layer is thicker.

10.08.5.1.2 Plume volcanism and partial melt zone

As mentioned in the preceding text, in one-plate planets, melt is usually generated underneath the lithosphere in places where the mantle temperature is higher than the mantle solidus. The melt can be produced either locally due to upwelling hot material, that is, mantle plumes, or more globally if the average mantle temperature is close to the solidus.

Whether a plume and associated volcanism can occur depends on the existence of a thermal boundary layer at the base of the mantle or at an internal chemical interface. Plumes are initiated in the boundary layers and are sustained by thermal instabilities. The existence of a thermal boundary layer at the bottom of the mantle requires sufficient heat flow from the core. If the mantle is mainly heated from within, plumes are very weak and the associated volcanism is either insignificant or not present. In this case, mantle convection is dominated by cold downwellings and the upwellings are broad with a small temperature contrast relative to the average mantle. Mantle convection and thermal evolution models show that planetary mantles of one-plate planets are mainly dominated by internal heating during a long period of their evolution. An exception can occur in the very early evolution if the core is superheated due to core formation or if sufficient heat is generated in the core due to the decay of radioactive heat sources. For example, potassium might be incorporated in the core at high pressure (Murthy et al., 2003). In case of a superheated core, heat flow from the core decreases rapidly a few hundred million years after core formation and the temperature difference across the CMB layer decreases rapidly to only a few tens of kelvins (Breuer and Spohn, 2003, 2006; Hauck and Phillips, 2002; Spohn et al., 2001). Convection models show that plumes cease or cannot even develop under these conditions (Spohn et al., 2001). The temperature difference at the CMB, which is the maximum excess temperature of the plume, can be increased to larger values of about 150 K if the viscosity increases with depth (Buske and Christensen, 2003). The excess temperature further decreases with height above the CMB because of adiabatic cooling and heat diffusion (Albers and Christensen, 1996) and in the presence of the exothermic phase transitions, for example, α- to β-olivine and β- to γ-olivine. In conclusion, one would expect only weak volcanic activity due to present-day plumes in a planet with one-plate tectonics. However, present plume volcanism is possible for the following reasons:

1. In case of a layered mantle due to a chemical interface or an endothermic phase transition, a thermal boundary layer can form at the interface of the convecting mantle layers where upwelling plumes may develop.
2. A strong increase of viscosity with depth.
3. Heat supply from the core due to radioactive elements or gravitational energy released due to the growth of an inner core.

The maximum excess temperature of these plumes, that is, the temperature jump across the thermal boundary, however, depends strongly on the heat source distribution within the mantle and the core, the mantle rheology, and the existence of phase transitions.

In contrast to strong mantle plumes, global melting can be present for a much longer time period, probably until the present, depending on the efficiency of mantle cooling and amount of radioactive heat sources. For example, a one-plate planet with a dry mantle, that is, a mantle with a stiff rheology, a thick low-conductivity crust, and a high concentration of radioactive elements in general shows that the average mantle temperature remains close to the solidus, which is a consequence of the Tozer (1965) equilibrium described earlier in the text. A typical evolution of an associated melt zone involves the downward propagation of its upper boundary with time as a consequence of planetary cooling. Thus, the average source region of the melt migrates to greater depth.

10.08.5.1.3 Thermal properties of the crust

The crusts of terrestrial planets can act as thermal insulators for the planets. The crust is enriched in radioactive elements and its thermal conductivity is lower than that of mantle material. The thermal conductivity of most compact volcanic materials ranges between 1.5 and 3.5 $W\,m^{-1}\,K^{-1}$ at ambient temperatures (Clauser and Huenges, 1995; Clifford and Fanale, 1985), but it decreases with temperature similarly to mantle material (Seipold, 1992). For example, the thermal conductivity of typical compact basalt decreases from about 2 $W\,m^{-1}\,K^{-1}$ at 270 K to about 1.5 $W\,m^{-1}\,K^{-1}$ at 800 K. In addition to the temperature effects on thermal conductivity, the structure of the material can significantly change the thermal conductivity. Fractured and porous materials have a reduced thermal conductivity in comparison to compact material. The upper crust of the terrestrial planets and the Moon has been fractured due to impact processes, in particular in the early period of heavy bombardment. These impacts resulted in the production of a porous megaregolith that extends to considerable depth, for example, to about 10 km for Mars (Clifford, 1993) and a few tens kilometers for the Moon (Binder and Lange, 1980; Wieczorek et al., 2013). A recent analysis of high-resolution data from the GRAIL mission to the Moon has also revealed a strong lateral variation of this megaregolith layer (Wieczorek et al., 2013). At the transition between fractured and coherent basements, the lithostatic pressure is sufficient to close all fractures and the intergranular pore space. It is expected that the porosity decreases exponentially from the dusty surface to this self-compaction depth (Binder and Lange, 1980). As a consequence, thermal conductivity decreases from the bottom of the megaregolith toward the surface. At low atmospheric pressures (e.g., around the ambient atmosphere pressure on Mars and lower), surface thermal conductivity can take on extremely low values. Remote thermal measurements for the Martian surface indicate soil thermal conductivities in the range of 0.075–0.11 $W\,m^{-1}\,K^{-1}$ (Kieffer, 1976), but it is assumed that thermal conductivity increases significantly in the first few centimeters, for example, to a value of about 0.5 $W\,m^{-1}\,K^{-1}$ (Helbert and Benkhoff, 2003), typical of sedimentary material or loose sandstone. The decrease of thermal conductivity due to porosity is less if the pores are filled, for example, with water ice. Furthermore, hydrothermal circulation in a porous, permeable regolith can counteract the low conductivity of the crust. This may be relevant for Mars since there are indications that the planet had a water-rich crust for much of its geologic history.

10.08.5.1.4 Observations

To study the crustal evolution and composition of the terrestrial planets, a combination of global spectral imaging, optical imaging, gravity measurements, and laser altimetry (remote sensing), in situ investigations, and laboratory analyses of returned samples is desired. Since there is a different level of planetary exploration for each of the terrestrial planets, our knowledge varies strongly among the planets with Mars and the Moon being the most studied bodies so far.

Mapping of the surfaces using image and topography data allows us to reconstruct geologic units. Of particular importance is the determination of the relative ages of different units by crater counting. In the case of Venus, the dense atmosphere does not allow us to obtain visible images of the surface, but with the radar on board the NASA Magellan mission, it was possible to study the surface with radar images and topography data, thereby allowing crater studies. In addition, the Visible and Infrared Thermal Imaging Spectrometer (VIRTIS) on board the Venus Express ESA mission was able to image most of the southern hemisphere in a window near 1 μm. The derived near-infrared (IR) surface emissivity provides information on differences in surface composition.

To obtain the absolute ages of the geologic units, direct samples from the planetary surfaces are required. These dated samples are available from the Moon but not for other terrestrial planets (Shergottite, Nakhlite, and Chassigny (SNC) meteorites that are believed to originate from Mars cannot be used due to the lack of knowledge of the geologic setting from where the meteorites came). Therefore, the cratering rate and the absolute ages of the Moon's surface are used to calibrate the relative surface ages of the other terrestrial planets. However, there is an uncertainty in the ratio of the specific planet/Moon cratering rates that propagates directly into uncertainty on age (**Chapter 10.10**). Despite this uncertainty, with the identification of volcanic areas and their ages, the image and topography data can also be used to estimate the amount of volcanic activity with time. However, one needs to consider that only extrusive volcanism can be observed at the surface but not intrusive material below the surface. Estimates of the relative proportion between intrusive and extrusive materials range from a factor of 7 to 10 (Greeley and Schneid, 1991), but this factor might vary strongly among the planets and the crustal formation processes. Further insight to the timing of crustal evolution can be obtained by the geochemical analysis of samples. Such studies exist for the Moon (Apollo samples) and Mars (SNC meteorites) that have

identified for both bodies an early mantle differentiation event with a major crustal formation event 4.5 Ga ago.

Seismology is the method of choice for determining crustal thickness on Earth. Seismic data are not yet available for the other terrestrial bodies (except lunar seismic data acquired during the Apollo exploration), although the deployment of seismometers on Mars is envisioned for future missions. In 2016, the NASA Discovery mission InSight plans to deploy one seismometer at the Martian surface to constrain its interior structure. In the absence of seismological data, however, the crustal thickness of terrestrial planets and the Moon is nonuniquely constrained by the gravity field and topography measurements (see **Chapter 10.05**).

The composition of the crust can be measured by a combination of different methods. The most reliable method is the examination of samples in the laboratory, possible so far for the Moon and Mars. Without direct access to samples, the mineralogical composition can also be assessed on a global scale by IR imaging spectroscopy in the range of 0.8–50 μm. This spectral domain contains a large number of signatures diagnostic of many minerals. This technique has revealed mafic to ultramafic compositions for flows on the surface of Mercury (Charlier et al., 2013) and generally mafic compositions (basalt to basaltic andesite) for the major surface units on Mars (Christensen et al., 2000; McSween et al., 2003). Mafic to ultramafic compositions are also inferred based on spectroscopically determined eruption temperatures on Io (McEwen et al., 1998).

For bodies without atmospheres, elemental compositions may be mapped from orbit using gamma or neutron spectrometry. Lunar Reconnaissance Orbiter (Lawrence et al., 1998), SELENE/Kaguya (Kobayashi et al., 2010), and Chang'E (Zhu et al., 2013) provided, for instance, maps of uranium, thorium, potassium, oxygen, magnesium, silicon, calcium, titanium, and iron. The data not only revealed correspondences with the surface features but also showed variations across previously undifferentiated units such as the far side highlands (Yamashita et al., 2010).

For in situ measurements, the alpha proton x-ray spectrometer technique has been used on the NASA Pathfinder mission to Mars and the Mars Exploration Rovers (MERs), Spirit and Opportunity, to chemically analyze soils and rocks without any sample preparation (except the use of a rock abrasion tool to analyze 'fresh' crustal material). Other in situ instruments are the Mössbauer spectrometer to determine with high accuracy the composition and abundance of iron-bearing minerals and the mini-thermal emission spectrometer to analyze the mineral composition of Martian surface features and select specific rocks and soils for more detailed investigations. Both instruments have been already used on the MER rovers. In situ measurements of the radioactivity of the Venusian crust were carried out by several Venera probes, revealing a wide variation (equivalent to granitic to basaltic compositions on Earth) in levels of heat-producing elements.

10.08.5.1.5 Incorporation of crustal growth in thermochemical evolution models

To calculate crustal growth and mantle differentiation in parameterized thermochemical evolution models, one usually assumes that both effects are regulated by the mantle convection speed (e.g., Breuer and Spohn, 2003; Fraeman and Korenaga, 2010; Grott et al., 2011a,b; Hauck and Phillips, 2002; Morschhauser et al., 2011; Schubert et al., 1990; Turcotte and Huang, 1990). In earlier models, crustal growth was simply proportional to the vigor of mantle convection and a fixed parameter measuring the efficiency of magma generation (Schubert et al., 1990; Spohn, 1991; Spohn and Breuer, 1993). These models show crustal production rates even when the mantle does not contain partial melt. In more recent parameterizations, the actual melt fraction as a function of the melting and mantle temperature is considered in more detail (Breuer and Spohn, 2003, 2006; Fraeman and Korenaga, 2010; Grott et al., 2011a,b; Hauck and Phillips, 2002; Morschhauser et al., 2011). The parameterizations in the literature are slightly different, for example, in how they incorporate the increase of the melting temperature due to continuous depletion of the mantle in crust-forming elements and how they include volcanic heat transport through the lithosphere (see succeeding text). However, at least in the case of Mars, they basically give similar results (Breuer and Spohn, 2003, 2006; Hauck and Phillips, 2002).

In the early evolution of a planet, typically the heat flow out of the lithosphere that is transported from the interior to the surface via volcanism is larger than the heat transported conductively. This mode of planetary heat transport is called the heat-pipe mode (O'Reilly and Davies, 1981) after the localized channels through which melt brings heat to the surface. Heat pipes are conduits that transfer heat and material from the base of the lithosphere to the surface via buoyant ascent. The lithosphere is then advected downward due to the volcanic loading and cools more efficiently, that is, the lithosphere is thickened and the geotherm is depressed by the advection. This cooling mechanism plays a substantial role even today for Jupiter's moon Io (Moore, 2001; O'Reilly and Davies, 1981) and in the early evolution for the terrestrial planets (Moore and Webb, 2013; Morschhauser et al., 2011; Spohn, 1991). Recently, it has been shown with 2-D convection models that in addition to altering the thickness and thermal structure of the lithosphere, heat pipes also influence the stress distribution (Moore and Webb, 2013). Lithospheric stresses are reduced by the combination of thickening and the loss of buoyancy from the convective thermal boundary layer at the top of the mantle through the heat pipes. As a consequence, the initiation of plate tectonics in the case of the Earth was possibly triggered at the end of the heat-pipe mode about 3.2 Ga ago due to increased lithospheric stresses sufficient to exceed the yield stress of the plate (Moore and Webb, 2013).

More recently, the thermochemical evolution of terrestrial planets, in particular for Mars, has been also calculated with 2-D and 3-D convection models (e.g., Golabek et al., 2011; Keller and Tackley, 2009; Nakagawa and Tackley, 2012; Ogawa and Yanagisawa, 2011; Plesa and Breuer, 2014; Ruedas et al., 2013a,b). These models do not require parameterizing the crustal growth with the convective vigor but instead calculating self-consistently the melt production and associated processes like depletion of heat sources and volatiles in the residual mantle whenever the local temperature exceeds the solidus temperature. In most models, it is assumed for simplicity that partial melt is instantaneously removed from the interior, although a few global models also consider the transport of melt via two-phase flow (Ogawa and Yanagisawa, 2011), and most models so far neglect the additional cooling due the downward migration of the lithosphere that can be important

for high crustal production rates (Moore and Webb, 2013). The models allow consideration of regional effects of melting that are necessary to study, for instance, the crustal dichotomy and large volcanic provinces of Mars and the mare volcanism on the Moon. Nevertheless, general trends as with the parameterized convection models have been identified with the 2-D and 3-D convection models, for instance, the interior temperature of a planet is significantly buffered in the case of melting due to the consumption of latent heat, the efficient transport of melt toward the surface, and the depletion of radioactive elements in the mantle.

10.08.5.2 Magnetic Field Generation

Magnetic field generation in the iron-rich core of a planet is strongly coupled to the thermal evolution of the planet. Thus, knowledge about the magnetic field evolution can be used to constrain the thermal evolution of a planet. Planetary space missions instrumented with magnetometers provide insight about the present magnetic fields of the terrestrial planets. The available data, however, differ significantly. In the case of the Moon, the lunar magnetic field has been studied indirectly via the natural remanent magnetization of the returned lunar samples and directly with magnetometers carried to the surface and placed in orbit at low altitude above the surface on the Apollo 15 and Apollo 16 subsatellites (see reviews in Dyal et al., 1974; Fuller and Cisowski, 1987). In 1998, Lunar Prospector allowed detailed global measurements of the magnetic field (Lin et al., 1998). In the case of Mars, Mars Global Surveyor (MGS) measured the magnetic field of the entire planet (Acuña et al., 1998). Both bodies, that is, the Moon and Mars, show no sign of a present internal field but parts of their crusts preserve a remanent magnetization (Acuña et al., 1999; Coleman and Russell, 1977). It is assumed that the remanent magnetization was established at the time of crustal formation, while an internal dynamo was active (Acuña et al., 1999; Runcorn, 1975). An age determination of the magnetized and nonmagnetized crust would thus allow us to reconstruct the magnetic field history. Estimates have been made for the Moon (e.g., Garrick-Bethell et al., 2009; Shea et al., 2012; Tikoo et al., 2012) and Mars (e.g., Arkani-Hamed and Boutin, 2012; Lillis et al., 2008, Mitchell et al., 2007).

In the case of Mercury, the two flybys by Mariner 10 have identified a weak internal field (Ness et al., 1974) – an observation recently confirmed by the NASA MESSENGER mission (Anderson et al., 2011). Venus, like Mars and the Moon, has no present-day dynamo action in its core. For both planets, Mercury and Venus, we cannot exclude the presence of an old magnetized crust because data are not available so far, but the temperature of the crust of Venus is likely close to the Curie point of magnetic minerals even at the surface suggesting – if existent at all – a thin magnetized crustal layer. As long as we do not know whether the crust is magnetized, we are unable to reconstruct the magnetic field history.

10.08.5.2.1 Core convection and necessary conditions for dynamos

To generate a self-sustained magnetic field, convection within the electrically conductive, metallic core is required. To obtain core convection, one must appeal to unusually large heat flows or the development of an inner core. In either case, the core must be cooling and the cooling is controlled by the heat transport of the outer layers, that is, the mantle and the crust (for a review, see Breuer et al., 2010).

10.08.5.2.1.1 Thermal dynamo

Thermal convection in the core, like thermal convection in the mantle, is driven by a sufficiently large superadiabatic temperature difference between the core and the mantle. It occurs if the core heat flow exceeds that conducted along the core adiabat. The latter heat flow, therefore, serves as a criterion for the existence of thermally driven convection in the core:

$$q_{\mathrm{crit}} = k_c \frac{\mathrm{d}T}{\mathrm{d}r} = k_c \frac{\mathrm{d}T}{\mathrm{d}P}\frac{\mathrm{d}P}{\mathrm{d}r} = k_c \frac{\alpha_c g_c T}{C_c} \qquad [22]$$

with k_c the thermal conductivity of the core, $\mathrm{d}T/\mathrm{d}r$ the temperature gradient in the core, P the pressure, α_c the thermal expansivity, C_c the heat capacity, and g_c the gravity. The critical heat flow varies between 5 and 20 mW m^{-2} for Mars (Nimmo and Stevenson, 2000) and Mercury and between 15 and 40 mW m^{-2} for Venus and is smaller than 7 mW m^{-2} for the Moon. The large variation in the value for each planet comes partly from the uncertainty in the thermal conductivity of the core material, which varies between 43 and 88 W m^{-1} K^{-1} at the core pressures (Anderson, 1998; Stacey and Anderson, 2001). However, it should be noted that recent advances in high-pressure mineral physics have indicated that the thermal conductivity (and thus the minimum heat flux for convection) of the Earth's core is likely a factor of 2 higher than previously thought – and thus higher values are also possible for other terrestrial planets. Calculated values of the thermal conductivity of the Earth's core range from 90 to 150 W m^{-1} K^{-1} (de Koker et al., 2012; Gomi et al., 2013; Pozzo et al., 2012).

The cooling of the core is strongly controlled by the thermal evolution of the overlying mantle. If the mantle removes heat from the core at a rate that exceeds the critical heat flow, then the core will convect. If the mantle removes heat at a rate less than the critical heat flow, the core is thermally stably stratified and dynamo action by thermal convection is not possible.

10.08.5.2.1.2 Chemical dynamo

Compositional convection can occur due to the release of positively buoyant material during the process of solid inner core freezing from a fluid core with noneutectic composition (Braginsky, 1964). The existence of light elements in the core has been assumed for all terrestrial planets (**Chapter 10.02**), and many suggestions have been offered for the amount and identity of the light elements that are mixed with the iron. For example, sulfur in the core – just as most other light elements in small enough concentrations – has two major effects: first, a reduction of the average density of the core and, second, a significant reduction of the melting temperature (e.g., Fei et al., 1997; Usselman, 1975). For most terrestrial planets, it is usually assumed that the composition of the sulfur-bearing core is on the Fe-rich side of the eutectic composition (e.g., Lodders and Fegley, 1998), whereas for the large Jovian moons (e.g., Scott et al., 2002) and Mars (e.g., Stewart et al., 2007), this is debated.

The conventional model of inner core growth on the Fe-rich side of the eutectic is applicable in cases where the (positive) slope of the core liquidus is steeper than that of the adiabat

(e.g., Stevenson et al., 1983). As a consequence, when the core has cooled to reach the liquidus at the center, iron will crystallize and an inner core nucleus will form and – upon further cooling – the core will freeze from the inside out. The outer core will be increasingly depleted in iron. The concentration of sulfur will not be homogeneous, though. Rather, a boundary layer will form just above the inner core where the sulfur concentration is above average. The fluid in this layer will be lighter than the remainder of the fluid core and compositional convection to homogenize the composition will be induced. Chemical convection can drive a dynamo more effectively than thermal convection (Braginsky, 1964; Stevenson et al., 1983). In contrast to the transformation of thermal energy to magnetic field energy, where only a small part of the energy is transferred (described by the Carnot efficiency factor, which is between 0.06 and 0.11; Lister and Buffett, 1995; Stevenson et al., 1983), a chemically driven dynamo has no similarly reduced efficiency.

Chemical convection and the associated generation of a magnetic field in the core occur if the temperature in the fluid (outer) core lies between the solidus and the liquidus of the core material. Inner core growth permits outer core convection even when the heat flow through the CMB is less than the heat carried by conduction along the adiabat.

Compositional convection, however, can be very different for sulfur-rich compositions or in smaller planetary bodies. For a sulfur-rich composition, solid FeS (or Fe_3S for pressures higher than 20 GPa) might precipitate deep within the core (Hauck et al., 2006; Stewart et al., 2007). Because of the high sulfur content of FeS (>36.5 wt% S), it is less dense than the residual liquid. The solid FeS thus buoyantly rises and remelts at higher levels. With decreasing temperature, the previous floatation and remelting of FeS increase the sulfur content near the CMB enough to raise the melting point of the liquid such that solid FeS is stable near the CMB resulting in the process of precipitation of FeS both deep and near the CMB (Hauck et al., 2006). The scenario described results in dynamics that are different from the Fe-rich side. In case of solid Fe_3S, it is assumed to be denser than the residual liquid and remains in the center to form an inner core as in the conventional Earth scenario (Stewart et al., 2007).

Recent experimental works (e.g., Chen et al., 2008; Chudinovskikh and Boehler, 2007; Fei et al., 1997, 2000; Stewart et al., 2007) have further identified two important aspects of the Fe–FeS phase diagram: (1) At pressures less than 14 GPa, the eutectic melting temperature decreases with increasing pressure, and (2) the S content at the eutectic decreases with increasing pressure.

A negative slope melting temperature in the core will have profound implication. For instance, Fe may precipitate at the CMB rather than in the center and may fall as iron snow. The solid iron particles are heavier than the surrounding Fe–FeS fluid, that is, a snow zone forms; settle to deeper core regions, where the core temperature is higher than the melting temperature; and remelt again. As a consequence, a stable chemical gradient in the Fe–FeS fluid arises within the snow zone (Hauck et al., 2006; Williams, 2009). The thickness of the snow zone increases with time, and below that layer, the fluid inner core is continuously enriched with remelting iron. This so-called iron snow regime process has been already suggested for the present magnetic field in Ganymede (Hauck et al., 2006; Rückriemen et al., 2014) and Mercury (Chen et al., 2008; Vilim et al., 2010), for a possible future chemical dynamo in Mars (Stewart et al., 2007) or for the early magnetic field on the Moon (Zhang et al., 2013) – although it is debated how and where a magnetic field can be generated in such a regime. Zhan and Schubert (2012) modeled fluid motions within the snow zone assuming that Fe snow resembles internally heated convection and obtain multipolar solutions for the magnetic field. On the other hand, Bland et al. (2009) and Williams (2009) argued that compositional-driven convection in the Fe snow zone does not provide enough energy to generate a magnetic field, while Rückriemen et al. (2014) argued that the style of convection via sedimentation is too small-scale and therefore lacks an important criterion necessary for dynamo action (Christensen and Wicht, 2007) as also shown by the dynamo models of Vilim et al. (2010). However, below the Fe snow zone, the process of remelting of iron creates a gravitationally unstable situation and it is proposed that this could be the driving mechanism for a potential dynamo (Rückriemen et al., 2014; Vilim et al., 2010). This dynamo scenario would be restricted to the time period the snow zone needs to grow across the core. Note that in the case of Mercury, it has been even suggested that multiple snow layers can exist in the core (Chen et al., 2008; Vilim et al., 2010).

In conclusion, whether a terrestrial planet has core convection and whether it can have a thermal or chemical dynamo depends on the cooling rate of the core, the core temperatures, and the core melting temperatures. If the mantle transports sufficient heat, then a dynamo occurs, but if the mantle is too insulating, then there is no dynamo.

Thermal evolution models indicate that the existence of a present-day magnetic field for a terrestrial planet is associated with the growth of an inner core. A present-day thermal dynamo is unlikely since the results show a slow cooling of a core with heat flow less than the heat flow along the core adiabat. In fact, a thermal dynamo is in general difficult to generate and only likely if the core is superheated with respect to the mantle due to the core formation process. If a thermal dynamo exists, it shuts off very early in the evolution as the heat flow out of the core decreases rapidly during the first few hundred million years. Whether in the subsequent evolution an inner core can grow and thus a compositional dynamo can be initiated depends strongly on the temperature evolution and the core composition.

10.08.6 Comparison of the Terrestrial Planets and the Moon

Although the evolution, composition, and interiors of terrestrial planets have some features in common, such as iron-rich cores, slowly convecting silicate mantles, and rigid crustal layers – they are entirely different in many other respects.

For instance, a strong diversity in crustal evolution has been identified: Mercury and the Moon show highly cratered surfaces, indicating an average crust older than about 4 Ga with only minor volcanic activity in the subsequent evolution. Mars shows a distinct dichotomy of the surface consisting of the old southern highlands with an average age of more than

4 Ga and the superficially younger northern lowlands with an average age of about 3.5 Ga (Tanaka et al., 1992). Below the comparative young surface, the northern crust has a similar age as the southern crust as concluded from topography data of partly buried impact structures (Frey et al., 2002). A continuous and rapid decline of global volcanism and crustal growth since planet formation can be observed in the surface morphology. Over time, global volcanism has been concentrated into mainly two volcanic regions, Tharsis and Elysium. In comparison to the other terrestrial planets, except the Earth, the average surface of Venus seems to be the youngest with an average crustal age of 300–800 Ma (McKinnon et al., 1997; Schaber et al., 1992).

Similar to crustal evolution, magnetic field evolution differs among the terrestrial planets and the Moon. Mercury is the only terrestrial planet, except the Earth, that has a magnetic field (Ness et al., 1974) – although a weak one – that is generated in the iron core (Jupiter's satellite Ganymede also shows an internally generated field; Kivelson et al., 1996). Venus, Mars, and the Moon on the other hand have no present global magnetic fields, but at least in the case of the Moon and Mars, the remanent magnetization of part of their crust indicates that they once had dynamo action in their cores (Acuña et al., 1999; Runcorn, 1975). The diversity in the volcanic and magnetic history of the bodies is also reflected in their thermochemical evolution. In the following sections, we will describe the thermal, volcanic, and magnetic evolution of the planets.

10.08.6.1 Mercury

After the three flybys of Mercury by the Mariner 10 spacecraft in 1974–75 that returned images of about 45% of the planet's surface, a wealth of information has been obtained since 2011 by the polar orbiter MESSENGER – information that not only confirmed our view of Mercury but also revised some previous assumptions about the interior structure, dynamics, and evolution of the interior.

The images of both missions revealed a lunar-like terrain with an average age of more than 4 Ga and lobate scarps that are more or less evenly distributed over the surface. Initially, the scarps were thought to indicate an average contraction of the planet's radius by 1–2 km since the end of heavy bombardment (Strom et al., 1975). Later, estimates of the contractional strains associated with lobate scarps as imaged both by Mariner 10 and by MESSENGER during its flybys implied a limited decrease of planetary radius of up to 0.8 km only (Watters and Nimmo, 2010; Watters et al., 1998, 2009). However, the data can be strongly biased by the illumination conditions at which the images were taken (Watters et al., 2009) and recent data collected during MESSENGER's orbital phase at high Sun incidence angles allowed Di Achille et al. (2012) to identify a number of previously undetected structures. These imply a revised value of the overall radius decrease of 2.8–3.6 km if wrinkle ridges are also taken into account, and in the most recent comprehensive study of contractional tectonics, an even larger value of 5–7 km has been inferred (Byrne et al., 2014).

The overall radius decrease provides an important constraint on the planet's thermal evolution. The most likely source of global contraction is a combination of a thermal contraction (reduction in average internal temperature) and a phase change by solidification (e.g., growth of an inner core). Core freezing contributes more to the global contraction. Complete core solidification would shrink the planet about 17 km in radius (Solomon, 1976), much more than required from the geologic observations. This effect can be considerably amplified if a light alloying element such as sulfur is present in the core. Light elements will be expelled from the inner core upon solidification, increasing the density difference between the liquid and solid core phases. A small inner core is therefore better to reconcile with a small planetary contraction. The total planetary radius change as a function of inner core size for different core bulk sulfur contents is shown in **Figure 5**. Already small inner core sizes of $R_i/R_c = 0.2$ result in global contraction of 1 km. For $R_i/R_c = 0.4$, the associated global contraction already exceeds the amount of contraction observed on the surface, posing severe constraints on the admissible inner core sizes.

Thermal evolution models (Grott et al., 2011a; Hauck et al., 2004; King, 2008; Schubert et al., 1988; Tosi et al., 2013a) indicate that the observed scarps strongly restrict the possible evolution scenarios of Mercury. One possible explanation is that much of the contraction would have predated the observable geologic record, for instance, most of the inner core was formed before the end of heavy bombardment (Schubert et al., 1988). Alternatively, the inner core started to grow only recently and is small (Grott et al., 2011a; Hauck et al., 2004; Tosi et al., 2013a). In any case, to meet the constraint of only 2.4–3.6 km of contraction since the end of heavy bombardment, relatively little cooling of the interior should have happened since that time, which requires a relatively stiff mantle (high reference viscosity), a low enrichment of radioactive elements in the crust, and a thin crust (Grott et al., 2011a; Tosi et al., 2013a). With the more relaxed constraint allowing a global contraction between 5–7 km (Byrne et al., 2014), these requirements are still valid but a slightly larger parameter variation is possible than shown in **Figure 6**. In particular, a more volatile-rich mantle, thus a lower reference viscosity is possible (Tosi, personal communication).

The thermal history of terrestrial planets depends strongly on the amount of radioactive elements in their interiors. Predictions for the abundances of the important heat-producing elements uranium, thorium, and potassium in Mercury depend on the formation scenario, which seems to be very special among the terrestrial planet, as indicated by Mercury's large bulk density of ~5430 kg m^{-3}. There are three general hypotheses for the formation of Mercury. The first scenario for forming Mercury's large bulk density involves aerodynamic sorting of iron and silicate particles in the solar nebula (Weidenschilling, 1978) that might have given the planet abundances of U and Th similar to the upper mantle of the Earth, though lacking much K (Basaltic Volcanism Study Project, 1981). The other two models for Mercury's formation involve a later stage loss of silicate, and retention of iron, materials. Impact-induced stripping of the outer, silicate layers of a larger, differentiated, proto-Mercury (e.g., Cameron et al., 1988; Wetherill, 1988) could have left a silicate layer with near CI chondritic abundances of heat-producing elements (e.g., Lodders and Fegley, 1998). A final, more exotic scenario involves a late-state vaporization of silicates that would result in a Th-rich silicate layer lacking appreciable U and K (Fegley and Cameron, 1987). Of the three formation models, the vaporization model predicts less cooling and contraction of the planet (Hauck et al., 2004) as it assumes ^{232}Th as the sole of radiogenic heat (Fegley and Cameron, 1987), which with its 14 Gy half-life has not had a significant decline in heat output. However, evidences for pyroclastic eruptions are documented in MESSENGER images and high magma volatile contents above >0.36 wt% are required to emplace pyroclasts to the observed distances (Kerber et al., 2011). A more volatile-rich content as previously assumed is also suggested by the measurements of the average surface abundance of the radioactive isotopes by the MESSENGER gamma-ray spectrometer (Peplowski et al., 2011, 2012). Both hint at a volatile content similar to other terrestrial planets and hence permit to rule out at least vaporization and condensation models as these require a nearly complete loss of volatiles.

To address this problem, Grott et al., (2011a) and Tosi et al. (2013a) reinvestigated the thermochemical evolution of Mercury using a nonrefractory compositional model, taking the presence of a thermally insulating regolith layer into account. Models with a stiff mantle rheology satisfy the observational constraints of contraction if the regolith layer is at least 2 km thick. Inefficient mantle convection and thermal insulation significantly slow planetary cooling and prolong the phase of crustal production to 2.5 Gy after core formation. The volume increase associated with mantle differentiation then offsets some of the radial contraction caused by planetary cooling (**Figure 6**). It should be noted though, at the relatively low oxygen fugacities of Mercury's interior, that can be inferred from the high S and low FeO content of the surface (Zolotov et al., 2013), elements such as K, Th, and U, which are usually lithophile, can become more siderophile (Malavergne et al., 2010). McCubbin et al. (2012a) thus pointed out that it is still uncertain whether Mercury's mantle is enriched in volatiles or not.

Low-degree coefficients of the gravity field obtained from the MESSENGER radio science experiment (Smith et al., 2012) combined with Earth-based radar measurements of the planet's spin state (Margot et al., 2007) have been used to revise the internal mass distribution (see also **Chapter 10.02**).

Before MESSENGER, Mercury's high density (e.g., Anderson et al., 1987) indicated already a massive core (e.g., Siegfried and Solomon, 1974). While a core radius of about 1800–1860 km (consistent to a mantle thickness of about 580–640 km) has previously been assumed in most thermal evolution models (e.g., Grott et al., 2011a; Hauck et al., 2004; Schubert et al., 1988), the new data and current interior structure models predict a significantly larger core (Hauck et al., 2013; Riner et al., 2008; Rivoldini et al., 2009). Mantle thicknesses between 300 and 500 km are possible, with intermediate values around 400 km being the most likely.

In general, a thinner mantle cools more efficiently than a thicker mantle and convection in a thin mantle possibly ceases faster. The need to understand whether mantle convection is currently ongoing or ceased in the past is also related to the interpretation of the gravity field and topography in terms of the interior structure of the planet. If the mantle is still convecting, deep-seated density anomalies and flow-induced dynamic topography of the surface and CMB may contribute to the observed fields. Michel et al. (2013) recently presented a parametric study of 2-D convection models. They analyzed the effects of different core radii between 1800 and 2100 km on the longevity of mantle convection and concluded that, for a sufficiently high rate of internal heat generation, convection can persist until the present day in a mantle at least 400 km thick. However, to further fulfill the constraint of small planetary contraction for values up to 5 km, Tosi et al. (2013a) argued that with a thin mantle of 400 km, present-day convection is unlikely. For the revised contraction value of 5–7km (Byrne et al., 2014), convection is still unlikely for a dry mantle but possible for a volatile-rich mantle (Tosi, personal communication). The planform of mantle convection in a thin mantle typically consists of several small-scale cells (**Figure 6**; Breuer et al., 2007; Tosi et al., 2013a). Regular long-wavelength patterns of linear rolls that were held responsible for the orientation of contractional strain associated with lobate scarp formation (King, 2008) can only be obtained with specific initial low-degree perturbations of the temperature field (Tosi et al., 2013a).

Due to the specific interior structure of Mercury, that is, the relatively thin mantle and the associated efficient cooling, it has been speculated that a pure iron core could be totally frozen very early in the evolution (Siegfried and Solomon, 1974; Solomon, 1976). Such a scenario is consistent with the geologic observation of small global contraction since the end of the heavy bombardment. A totally frozen core, however, is difficult to reconcile with the magnetic field history of Mercury. During the first and third close encounters in 1974 and 1975, Mariner 10 passed briefly through a small but earthlike magnetosphere. The analyses of these observations revealed the presence of an internal field, with a dipole moment that is a factor of about 10^4 smaller than that of the Earth (Ness et al., 1974, 1975, 1976; Russell et al., 1988; see review in Connerney and Ness, 1988) – findings that have been confirmed with the MESSENGER mission (Anderson et al., 2011). The discovery of the internal field strongly suggests the presence of a fluid outer core. To prevent the core from freezing, the addition of radioactive heat sources into the core (Toksöz et al., 1978), a late core formation (Sharpe and Strangway, 1976; Solomon, 1977), or deep mantle heat sources (Cassen et al., 1976) has been suggested. Late core formation would support a cool initial state for Mercury but is at variance with accretion models (e.g., Schubert et al., 1988). The most likely reason for Mercury not having a totally frozen core, however, is the incorporation of a light alloying element into its core that reduces the core melting temperature. Here, sulfur is the most likely candidate (McCammon et al., 1983; Ringwood, 1977) although strong chemically reducing conditions indicated by MESSENGER XRS measurements of surface materials (Nittler et al., 2011) suggest a core containing Si and S (Malavergne et al., 2010) that may have strong implication on the core structure and evolution (Hauck et al., 2013; Smith et al., 2012).

The amount of sulfur depends on the formation scenario of Mercury. In the most conservative equilibrium condensation models, there is no sulfur at all in the Mercurian core due to the close position of the planet to the Sun (Grossman, 1972; Lewis, 1972), an assumption mostly used in earlier thermal evolution models (Sharpe and Strangway, 1976; Siegfried and Solomon, 1974; Solomon, 1976, 1977). However, a low concentration of sulfur has been suggested with radial mixing of planetesimals and/or nonequilibrium condensation models (Basaltic Volcanism Study Project, 1981; Wetherill, 1985). Mercury's inner structure that is consistent with its high density can actually be explained with a wide range of the sulfur concentration in the core ranging from a pure iron core to a core with eutectic Fe–FeS composition (Harder and Schubert, 2001).

The observation of the magnetic field provides probably the best constraint on the interior evolution, and assuming that it is indeed generated in the core and not a remnant field – as on Mars – it proves that there is a present convecting outer core. The existence of the fluid outer core places constraints on the maximal sulfur content in the core. The inferred small planetary contraction from the lobate scarp, on the other hand, places constraints on the minimal amount of sulfur in the core (Breuer et al., 2007; Grott et al., 2011a; Hauck et al., 2004; Tosi et al., 2013a). In general, one can state that the less efficient the planetary cooling, the smaller is the required sulfur content.

Thermochemical evolution models based on temperature-dependent viscosity laws that couple the thermal, magmatic, and tectonic evolution of Mercury (Hauck et al., 2004) indicate that a dry non-Newtonian mantle and early crustal formation allows the planet to cool more efficiently than a dry Newtonian mantle. The more crust is produced, the stronger is the mantle cooling and the associated depletion of the mantle in heat sources. As a consequence, acceptable models for the sulfur content range between 6.5 and 7.5 wt% S to explain the observations and require a late formation of the inner core. A similar result has been suggested by the thermochemical models of Grott et al. (2011a) and Tosi et al. (2013a), further considering the isolating effect of the regolith layer and a nonrefractory composition.

The thermal evolution models (Buske, 2006; Grott et al., 2011a; Hauck et al., 2004; Schubert et al., 1988; Tosi et al., 2013a) show a typical evolution of the magnetic field: in the early evolution, a dynamo is generated by thermal convection before the start of the inner core and a chemical dynamo. Whether the dynamo action ceases for a time until inner core growth provides sufficient energy depends on the onset time of inner core growth. The higher the sulfur content, the later is the onset of inner core growth (e.g., Grott et al., 2011a; Hauck et al., 2004; Schubert et al., 1988; Tosi et al., 2013a). A detection of remanent magnetized crust and the

determination of its age by future missions could therefore help to constrain the amount of sulfur in the core and thus the formation scenario.

The hydromagnetic dynamo as assumed in the thermal evolution models in the preceding text poses a problem in the strength of the calculated field. Although there is presently no satisfying parameterization to calculate the magnetic field strength, estimates suggest a much larger field than that observed (Schubert et al., 1988; Stevenson et al., 1983). Recent thin-shell dynamo models, however, have shown that planets with a large solid inner core (relative inner core size larger than about 0.8) can produce magnetic fields with Mercury-like field intensities (Heimpel et al., 2005; Stanley et al., 2005). Alternatively, a deep dynamo model that suggests a rather small inner core (smaller than 1000 km in radius) has been proposed by Christensen (2006). In this model, the dynamo operates only at depth and the associated dynamo field is strongly attenuated by the skin effect through a stable conducting region of the upper core but can only explain the observed strength of the surface magnetic field when the sulfur concentration in Mercury's core is only a fraction of a percent (Manglik et al., 2010) – possibly not consistent with the thermochemical evolution of Mercury (Grott et al., 2011a; Hauck et al., 2004; Tosi et al., 2013a).

All the latter mentioned dynamo models assume the common earthlike dynamo for which iron starts to crystallize in the core center. The melting behavior of the iron–sulfur system at moderate pressures, however, suggest a negative liquidus temperature gradient under conditions found at shallow depths in Mercury's core. At the present time, the core is most likely precipitating solid iron in the form of snow, at a single depth or in two distinct zones (Chen et al., 2008). Dynamo models considering an iron snow zone midway through the core can produce the observed field strength (Vilim et al., 2010). Considering a Fe–S–Si ternary system in the core (e.g., Malavergne et al., 2010), experiments have demonstrated the immiscibility of S- and Si-rich liquids up to a pressure of ~15 GPa (Morard and Katsura, 2010; Sanloup and Fei, 2004) and smaller density differences between liquid and solid compared to the Fe–S binary system (Kuwayama and Hirose, 2004). These findings suggest a compositional stratification in the core as S-rich liquids would segregate toward the CMB leaving more Si-rich materials deeper (Hauck et al., 2013; Smith et al., 2012). The consequences of such a system on the dynamo generation are, however, unknown.

Another alternative way of generating a weak magnetic field in Mercury is by a thermoelectric dynamo (Giampieri and Balogh, 2002; Stevenson, 1987). This dynamo makes use of a thermoelectric electromotive force set up at a distorted CMB. Such a dynamo requires topography variations of the CMB of the order of a few kilometers due to mantle convection. Which kind of dynamo is active in Mercury cannot be concluded from the current magnetic data. New insights into the magnetic field evolution and the dynamo mechanism of Mercury are expected from the coming BepiColombo mission.

Among the new findings by MESSENGER is the observation that the volcanism probably lasted well into the second half of solar system history (Head et al., 2011; Prockter et al., 2010), while Mariner 10 images showed no evidence for substantial additions to the crust after the end of the late heavy bombardment (e.g., Spudis and Guest, 1988). Volcanic activity that extends a few billion years can be obtained considering a thermally isolating crust and regolith layer (Breuer et al., 2007; Grott et al., 2011a). Furthermore, x-ray spectrometric measurements of the surface materials revealed higher Mg/Si and lower Al/Si and Ca/Si ratios than typical terrestrial or lunar crusts (Nittler et al., 2011). These ratios are indicative of compositions intermediate between basaltic and ultramafic rock types, possibly comparable to terrestrial komatiites, and thus hinting at an origin from partial melts at melt fractions as high as 20–30%. Estimates of the crustal thickness have a large possible range. Anderson et al. (1996) used the observed center-of-mass and center-of-figure offset together with an assumption of Airy isostasy to infer a crustal thickness of 100–300 km. Further, constraints on the crustal thickness have been derived from viscous topographic relaxation (Nimmo, 2002). If the faulting observations provide a reasonable guide to heat fluxes on Mercury at 4 Ga, topography is most likely to have survived if the mean crustal thickness were less than 200 km. Studies employing topographical information about the Mercurian surface (Nimmo and Watters, 2004; Watters et al., 2004) suggest that the extensional faulting of observed lobate scarps is consistent with a mean crustal thickness of 90–140 km. The most recent gravity and topography data from MESSENGER by Smith et al. (2012) suggest an average value of 50 km assuming a density contrast of only 200 kg m^{-3} between the mantle and crust.

Thermochemical evolution models with parameterized stagnant lid convection and assuming an earthlike mantle for Mercury derive crustal thicknesses that vary between 5 and 70 km depending on the initial temperature distribution, the assumed amount of radioactive elements, and the mantle rheology (Breuer et al., 2007; Grott et al., 2011a; Hauck et al., 2004; Tosi et al., 2013a). However, with a mantle thickness of ~400 km, crustal thicknesses between 10 and 20 km are more likely (**Figure 6**) as a thicker crust tends to result in stronger contraction after the LHB, inconsistent with the observations.

10.08.6.2 Venus

The statistically uniform distribution of impact craters prevents us from identifying older or younger regions and thus from determining resurfacing rates. The surface has a global average age of 300–800 Ma (McKinnon et al., 1997; Schaber et al., 1992). From geochemical measurements of the Soviet landers, the surface appears to be basaltic (McKenzie et al., 1992) although there is a range of compositions, an observation that is supported by Magellan radar images. These images show many long volcanic flows that are similar to basaltic flows on Earth. It has been suggested that the entire surface was covered by a volcanic event of global-scale (McKinnon et al., 1997), but such an event is not required by the crater distribution (Bjonnes et al., 2012). In such models, the resurfacing event was followed by almost no volcanic activity to the present day. The cause for this global resurfacing event and whether it was a single event or one of a periodically recurring set of events is highly uncertain. Thus, a number of papers that speculate on the global resurfacing event can be found in the literature (e.g., Bougher et al., 1997; Nimmo and McKenzie, 1998; Turcotte, 1993):

1. Widespread melting is caused by a transition from layered to whole mantle convection (Steinbach and Yuen, 1992). As Venus is cooling, the tendency for mantle layering that is caused by the endothermic spinel-to-perovskite phase transition decreases until the layered structure breaks up with a single catastrophic event.
2. Periodic instabilities of a depleted layer beneath the crust (Herrick and Parmentier, 1994; Parmentier and Hess, 1992) result in the global melting event. In that scenario, the competition between compositional stratification due to crustal formation and thermal buoyancy may cause episodic overturn of the mantle.
3. The resurfacing is associated with a transition from oscillatory to steady convection due to planetary cooling and thus a decreasing Rayleigh number (Arkani-Hamed et al., 1993).
4. The global resurfacing has been related to some kind of episodic plate tectonics. After a resurfacing event, the cold lithosphere has been subducted, and a new lid grows conductively. As this lid thickens, its negative buoyancy increases, until at some critical thickness, it is able to subduct again and thereby instigates a new resurfacing event (Armann and Tackley, 2012; Fowler and O'Brien, 1996; Moresi and Solomatov, 1998; Turcotte, 1993; Weinstein, 1996). Herrick (1994) concluded that a change in surface boundary condition could lead to a rapid rise in mantle temperature and catastrophic resurfacing in the form of plate subduction.
5. Solomatov and Moresi (1996) assumed that the resurfacing event is caused by the cessation of plate tectonics. The reduction in convective stresses with time might cause deformation in the stagnant lid to change from brittle (plate tectonics) to ductile (little surface movement).

The commonly assumed rapid global resurfacing event has been questioned by Campbell et al. (1999) and more recently by Bond and Warner (2006) and Bjonnes et al. (2012). According to the latter authors, the cratering record allows a variety of interpretations in terms of volcanic resurfacing including a global decrease with time in the rate of an otherwise statistically distributed volcanic activity. Previous authors had concluded that Venus underwent a major transition in tectonic style albeit more gradual than the previously postulated sudden global resurfacing event. The surface geology also seems to indicate that modifications of the surface are planetwide and gradual over long periods of time rather than episodic and locally confined (Ivanov and Head, 2006). Whether there is present-day volcanic activity on Venus is unclear. Some sulfuric clouds have been interpreted as being evidence of recent volcanism (Fegley and Prinn, 1989). Recent data from the IR spectrometer VIRTIS on Venus Express (Helbert et al., 2006; Smrekar et al., 2010) suggest differences in surface temperature (emissivity) that can be linked to morphological features on the surface, indicating changes that are more rapid than the global weathering processes (10^5–10^6 years).

The significant correlation between the geoid and topography at low degrees, together with a relatively high admittance ratio, may indicate that a significant portion of the long-wavelength topography has a dynamic origin by mantle convection (Pauer et al., 2006; Simons et al., 1997). However, it should be noted that, as numerical investigation of convection in strongly temperature-dependent viscosity fluids has progressed, it has become apparent that temperature variations in the nearly stagnant conducting lid are the primary source of topography (Moore and Schubert, 1997; Solomatov and Moresi, 1996) and not dynamic stresses, which dominate at low Rayleigh number and small-viscosity contrast. Thus, topographic rises are not so much held up by upwellings as they are buoyed by the heat delivered to the lithosphere. Plume activity has been suggested by Moore and Schubert (1997), using a model of thermal isostasy. The authors found a very thick thermal lithosphere (200–400 km), which is locally thinned by up to a factor of 5 beneath the volcanic rises. This was attributed to convection in Venus' mantle at a Rayleigh number of about 10^7 and a large viscosity contrast based on the dynamic calculations of Solomatov and Moresi (1996). Similar conclusions are given by Phillips (1994) and Kucinskas and Turcotte (1994).

The influence that the resurfacing event must have had on the thermal history of Venus depends on the resurfacing mechanism. In comparison to the Earth, the question of early plate tectonics on Venus, which has been suggested by several papers, is particularly interesting. But unlike for Mars, there is little present evidence for it. However, it is likely that the main topographic features of plate tectonics, that is, ridges, trenches, and transform faults, may disappear during the 500 Ma after plate tectonics has stopped. Plate tectonics on Earth can take place because the driving forces, that is, slab pull and ridge push, exceed the resistive forces, that is, fault friction, flexure, and viscous drag (Forsyth and Uyeda, 1975). It is commonly suggested that water on the surface of Earth reduces the resistive forces by modifying the rheology of the cold plates such that subduction becomes feasible. The high D/H ratio in the Venusian atmosphere suggests that Venus had substantial water in the past (Fegley, 2004). Today, Venus is desiccated as far as the available spacecraft data can tell. Thus, present plate tectonics are not feasible if water on the surface is required (Nimmo and McKenzie, 1998). Another possible explanation for the present-day lack of plate tectonics on Venus is that the high surface temperature and thick basaltic crust make the lithosphere less dense than the underlying convecting mantle – subduction is inhibited (Herrick, 1994). Alternatively, the high surface temperature may reduce lithospheric stress by reducing the viscosity throughout it (Lenardic et al., 2008; Noack et al., 2012). Furthermore, a high mantle viscosity might cause a large viscous drag force on any moving plates (McKenzie, 1977). On Earth, this mantle drag is greatly reduced by the effect of the low-viscosity zone. For Venus, it has been suggested on the basis of the interpretation of gravity and topography data that a low-viscosity zone beneath the lithosphere does not exist (Kiefer et al., 1986; Nimmo and McKenzie, 1996). Recent models by Pauer et al. (2006) and Steinberger et al. (2010) show that the best fit to the data implies a gradual increase in viscosity.

Another important aspect of the thermal evolution of Venus is the coupling of the atmosphere or hydrosphere with the dynamics of the solid interior. The thick CO_2 atmosphere of Venus results in enhanced surface temperatures due to the greenhouse effect. The surface temperature, which is the upper thermal boundary condition of the convecting interior, on the other hand, influences the heat transport and thus the thermal evolution. These effects have been neglected so far in most

evolution models. A first attempt has been made by Phillips et al. (2001a) who investigated a coupled evolution for Venus using a simple parameterized mantle convection model (including partial melting) and a radiative–convective atmospheric model. Feedback was incorporated by the release of water associated with melt extraction into the Venusian atmosphere, which adds to the greenhouse effect and thus affects the surface temperature. After 2 billion years of evolution, the coupled model was hotter by several tens of kelvins and its extrusive volcanic flux was four times higher than the case without coupling. Their study showed a complex interplay between Venus convective evolution, volcanic activity, and atmospheric state even with such a simple model featuring only basic processes. More complex and elaborate models have been constructed (Lenardic et al., 2008, Noack et al., 2012, Smrekar and Sotin, 2012), demonstrating that the Venusian atmosphere and interior behave as a coupled system and must be considered as such.

Volcanic features on Venus include several large highlands topped by massive volcanoes, a large number of comparatively small shield volcanoes that are apparently randomly distributed, volcanic plains, and about 500 coronae – circular large-scale volcanic–tectonic features. It is widely accepted that coronae form above upwelling plumes (Smrekar and Stofan, 1999). Johnson and Richards (2003) reanalyzed the coronae distribution and had concluded that corona activity is concentrated in the Beta, Atla, and Themis rift systems.

The thickness of the crust has been constrained using gravity and topography data and estimates of the average thickness are about 35 km (Konopliv and Sjogren, 1994; Simons et al., 1994). Thermal evolution models with parameterized convection suggest that Venus may have a 100 km thick lithosphere, which may consist largely of basalt (Spohn, 1991), which has been confirmed by 2-D dynamic models (Armann and Tackley, 2012). This is inconsistent with the gravity results. Those parameterized models, however, assume one-plate tectonics throughout the entire evolution; that is, the crust was not recycled due to either plate tectonics or some other mechanism at the time of resurfacing. Furthermore, as Turcotte (1989) had noted, the thickness of the Venusian crust may be limited by the basalt to eclogite phase transformation that occurs at depths of 30–70 km, depending on the temperature (Ito and Kennedy, 1971; Ringwood, 1975). The dense eclogite phase is gravitationally unstable with respect to the mantle below. When the crust is sufficiently thick, crustal delamination may occur. Crustal thickness variations exist between the various geologic provinces: estimates are between 20 and 50 km at the volcanic rises (Phillips, 1994; Smrekar, 1994), 20–40 km in the plains (Grimm 1994; Konopliv and Sjogren, 1994), and 35–60 km around tessera sites (Grimm, 1994; Kucinskas and Turcotte, 1994; Moore and Schubert, 1997; Simons et al., 1994). The elastic thickness of the lithosphere ranges between 10 and 50 km (Brown and Grimm, 1996; Johnson and Sandwell, 1994; McKenzie, 1994, McKenzie and Nimmo, 1997; Phillips, 1994; Sandwell and Schubert, 1992; Smrekar, 1994), with a clustering around 30 km. Anderson and Smrekar (2006) demonstrated that models that include bottom loading show a larger range of local scales in the crustal thickness and the elastic lithosphere thickness than previous models. The results indicate that geologic processes may be very complex on Venus.

Since the first flyby of Venus by Mariner 2 in 1962 at a distance of 6.6 planetary radii, it was clear that Venus does not have an earthlike magnetosphere. In fact, the following mission of Mariner 5, in 1967, placed an upper limit on the magnetic dipole moment of Venus of $\sim 10^{-3}$ times that of Earth. Later, most definitive measurements of the magnetic moment of Venus were obtained during the Pioneer Venus Orbiter mission in its first years of operation (1979–81). The upper limit on the dipole moment obtained from the Pioneer Venus Orbiter placed the Venus intrinsic magnetic field at less than about 10^{-5} times that of Earth (Russell et al., 1979a,b).

The lack of a present dynamo does not imply that Venus never had an intrinsic magnetic field although we have no information that relates directly to the past history of the field. The surface temperature of about 740 K is relatively close to the Curie temperature (T_{curie}) of the main magnetic carriers on terrestrial planets, such as magnetite, hematite, and pyrrhotite with T_{curie} of 850, 940, and 600 K, respectively (e.g., Dunlop and Özdemir, 1997). Thus, temperatures of the crust – except possibly in an upper thin layer – are expected to be higher than the Curie point (at temperatures below the Curie point, magnetization could persist in rocky materials). Any remanent crustal magnetic field from an early period of dynamo activity might be weak on Venus if existent at all. It is also important to note that the slow rotation of Venus (a Venus day of $\sim$243 Earth days is almost equal to the length of its year of $\sim$224 days, and its sense of rotation is retrograde) does not exclude dynamo action.

Thermal evolution models suggest that there was a magnetic moment of Venus of the same order as the Earth's for about the first 3 billion years of Venus' history (Stevenson et al., 1983; see **Figure 7**). During that time, thermal convection drove the dynamo as suggested for the other terrestrial

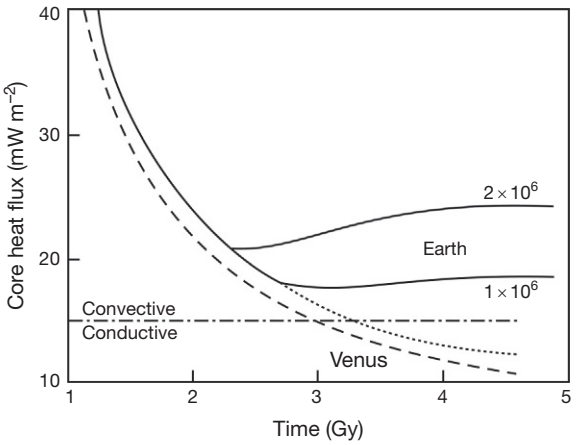

Figure 7 The heat flow out of the cores of Earth (solid and dashed lines) and Venus (dotted line) as a function of time. The curve parameter for the models is the specific energy release upon inner core freezing in J kg^{-1}. The dash-dotted line marks the conducted heat flux along the core adiabat. Without inner core solidification, larger heat fluxes indicate thermal convection in the core. Smaller heat fluxes are then indicative of cessation of thermal convection and dynamo generation. With inner core growth, chemical buoyancy helps to drive convection and the core heat flux may be sub- or superadiabatic. Reproduced from Stevenson DJ, Spohn T, and Schubert G (1983) Magnetism and thermal evolution of the terrestrial planets. *Icarus* 54: 466–489.

planets. After the core cooled below the adiabatic heat flow of the core, the magnetic field ceased and did not rejuvenate; the core was too hot and the pressure is too low for inner core growth. The evolution models by Stevenson et al. (1983) have been calculated with the parameterization based on constant viscosity laws, which are more representative for planets with lithosphere delamination (see **Sections 10.08.4.1** and **10.08.4.2**). Assuming that Venus was in a stagnant lid regime throughout the entire evolution, the phase of early dynamo action would be significantly reduced because core cooling might be overestimated with the former models.

An alternative scenario for the present lack of a Venus magnetic field suggests that Venus' field ceased as Venus transitioned from a plate tectonic to a stagnant lid regime around 700 Ma ago (Stevenson, 2002). As suggested for Mars (Nimmo and Stevenson, 2000), the transition heated the mantle and the core. If Venus had an inner core but a mantle temperature increasing in time, then the inner core would have ceased to grow (it may actually be shrinking in radius) and the dynamo could not be driven by chemical buoyancy released upon inner core growth.

10.08.6.3 The Moon

The thermal evolution of the Moon has been a controversial subject. Early models start the evolution of the Moon with an accretionary initial temperature profile. This temperature profile increases from a relatively cold deep interior (less than 1000 K) to reach a maximum in the upper mantle from where temperature decreases toward the surface (Matsui and Abe, 1986). Similar temperature profiles have been used in other models of the Moon's thermal evolution (Cassen and Reynolds, 1973; Cassen et al., 1979; Toksöz et al., 1978). Some of these authors have assumed a magma ocean overlying a cold interior. It has been argued that the absence of global-scale extensional or compressional features on the lunar surface limits variations in the lunar radius to ± 1 km over the past 3.8 Gy (Solomon and Chaiken, 1976). A recent analysis of the Lunar Reconnaissance Orbiter further identified undetected landforms that indicate even recent global shrinking of the Moon (Watters et al., 2010). Solomon and Chaiken (1976) found that for this radius constraint to be satisfied, the contraction due to cooling of the outermost layers of the Moon, which they assumed to be the crystallized product of the magma ocean, must be balanced by radioactive heating of the deeper interior. They argued that this constraint limits magma ocean depths to less than 400 km. Kirk and Stevenson (1989) indicated that a 630 km deep magma ocean can be allowed if contractional cooling of the magma ocean is partially offset by volume changes due to partial melting and chemical differentiation.

There is evidence, however, from the trace element pattern and the remanent magnetization of the Moon's surface rock that the Moon started hot or that the interior heated rapidly after accretion (Binder, 1986; Palme et al., 1984; Runcorn, 1977). The mechanism by which the lunar interior may have been rapidly heated has been the subject of debate. Among the possible mechanisms that have been discussed are the decay of short-lived radionuclides such as ^{26}Al, tidal heating, and electromagnetic heating, none of which are very satisfying because they did not provide heat at the right time or enough heat. The hypothesis of a giant impact origin of the Moon, however, provides a way of accreting the Moon hot (Stevenson, 1987) if the Moon forms more rapidly than the vapor that is ejected from the Earth cools.

More recent evolution models assume an initially hot interior but still open are questions about the thermal and structural state of the Moon after freezing of the magma ocean and whether convection is an important form of heat transport in the lunar interior. It is generally accepted that the anorthositic crust of the Moon formed as a floating crust on a magma ocean. Estimates of the depth of the primordial magmasphere depend on the assumed Al_2O_3 content in the primordial mantle and the assumption that either all Al_2O_3 is incorporated into the plagioclase crust (e.g., Warren, 1985) or some are crystallized also in the Al-bearing Mg–Fe minerals and remained in interstitial melts (Elkins-Tanton et al., 2011). The depth then varies approximately between 400 and 1000 km. Note that the crustal thickness has been recently revised to between 34 and 43 km (Wieczorek et al., 2013); before GRAIL, the average thickness of the Moon's crust was thought to be close to 50 km (Ishihara et al., 2009; Wieczorek et al., 2006). The freezing time of the magma ocean is estimated to last several hundred million years (e.g., Meyer et al., 2010; Minear and Fletcher, 1978; Shearer et al., 2006; Solomon and Longhi, 1977) also to explain the wide range of anorthositic crustal ages (e.g., Borg et al., 2002). In fact, the formation of the anorthositic crust, which acts as an insulating layer for the freezing magma ocean, together with tidal heating from the Earth may be responsible for the respective long time of solidification (Meyer et al., 2010) in contrast to a planet where magma remains at the surface during the solidification process (Elkins-Tanton, 2008). It is assumed that the magma ocean most likely became chemically stratified following its differentiation and crystallization with the late dense iron-rich phases coming to rest upon a less dense Mg-rich phase (apart from the floating anorthositic crust) (e.g., Hess and Parmentier, 1995). Petrologic studies (e.g., Snyder et al., 1992) have shown that this layering will consist of thick layers of olivine and orthopyroxene at the bottom, after which plagioclase crystallizes and floats. One of the last minerals to crystallize is the high-density ilmentite with pyroxene to form an ilmenite-rich layer and, finally, the so-called KREEP layer that is enriched in incompatible and heat-producing elements and sandwiched between the crust and the ilmenite-rich layer, leaving the mantle strongly depleted in radioactive heat sources (**Figure 8**).

Such a layering has strong implications for the subsequent evolution of the Moon since it is prone to convective overturn and mixing (Alley and Parmentier, 1998; Hess and Parmentier, 1995). It has also been speculated that during most of the Moon's history (i.e., after the first rapid overturn), heat might be transported by conduction alone (Kirk and Stevenson, 1989; Pritchard and Stevenson, 1999; Wieczorek and Phillips, 2000) as a consequence of the strong depletion of radioactive elements and the stable chemical layering in the mantle.

Whether the rapid convective overturn scenario took place and whether a subsequent stable chemical layering developed depend on the initial depth of the magma ocean and the freezing mechanism of the magma ocean. For instance,

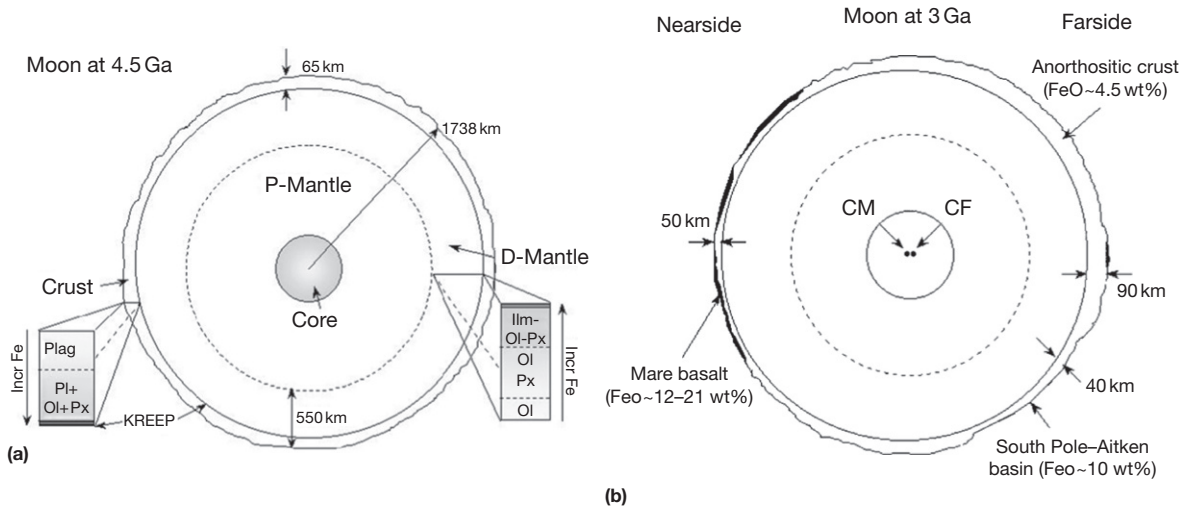

Figure 8 (a) A schematic cross section (roughly to scale) through the Moon immediately after crystallization of the magmasphere. The dashed line represents the 550 km seismic discontinuity. P-mantle is primitive mantle (unmelted or partially melted). 3-D mantle represents differentiated mantle. The sequence of cumulates in the upper mantle shows an upward enrichment in iron with a KREEP layer at the top sandwiched between the crust and mantle. The crustal cumulates are presumed to become more mafic and more iron-rich with increasing depth. (b) A schematic cross section through the Moon at 3 Ga. Note the thick farside crust and the giant South Pole–Aitken basin. CM, center of mass; CF, center of figure. The thickness of mare basalts on the nearside is exaggerated. The FeO concentrations are based on Clementine data (Lucey et al., 2000). Reproduced from McCallum IS (2001) A new view of the Moon in light of data from Clementine and Prospector missions. *Earth, Moon and Planets* 85–86: 253–269.

Elkins-Tanton et al. (2002) showed that the sinking of a solid dense ilmenite cumulate is unlikely because the temperatures at which the cumulates solidify is low, and thus, the viscosity is very high, keeping this layer close to the surface. A possibility to allow this layer to sink, however, is the entrainment of olivine during crystallization. On the other hand, Spohn et al. (2001) showed with 2-D and 3-D convection models that the deep layers of a 700 km deep magma ocean were kept (partially) molten over a significant part of lunar history. It is not well understood whether an unstable chemical layering would develop under these conditions at all. Furthermore, it is likely that the deep layers became chemically rejuvenated by the convective mass flow. The situation is different for a shallow magma ocean. In the case of a 300 km deep magma ocean, a melt zone forms below the magma ocean's original depth in the previously solid residual and convecting mantle; the layering of the freezing magma ocean would most likely not be disturbed but it is even more uncertain whether the unstable dense layers are thick enough to initiate a rapid overturn. In the case of thermal convection of the lunar interior, the evolution is found to be characterized by the growth of a massive 700–800 km thick lithosphere while the lower mantle and core cool only by a few hundred kelvins (Spohn et al., 2001); this is the typical evolution of a one-plate planet.

Based on the different assumptions how the crystallizing magma ocean evolved, the models of the thermochemical evolution of the Moon can be distinguished depending on the assumed initial chemical structure of the mantle. One group (Konrad and Spohn 1997; Laneuville et al., 2013; Spohn et al., 2001; Ziethe et al., 2009) considers a mantle with uniformly distributed composition and heat-producing elements. The mantle is, however, depleted in heat sources as these are enriched in a KREEP layer and distributed either homogeneously (Konrad and Spohn, 1997; Spohn et al., 2001; Ziethe et al., 2009) or laterally inhomogeneous (Laneuville et al., 2013) below the crust. Another group (de Vries et al., 2010; Parmentier et al., 2002; Stegman et al., 2003; Zhang et al., 2013; Zhong et al., 2000) considers a compositionally stratified mantle including an inhomogeneous distribution of the radioactive heat sources as a consequence of magma ocean cumulate overturn. The latter is driven by the dense, ilmenite-bearing cumulates that sink into the mantle and perhaps to the CMB (e.g., Hess and Parmentier, 1995). Both model approaches can not only explain some observations but also have difficulties that will be described in more detail in the succeeding text.

The Moon has been divided into two major geologic terranes, the highlands and the maria. The highlands are more cratered and higher in elevation than the darker maria. The bulk of the highland crustal rocks, consisting of ferroan anorthosites, is formed as a floating crust on a magma ocean during the first 100–200 Ma (Lee et al., 1997). The maria are impact craters filled by basaltic lava. The basaltic lava, the most prominent witnesses of volcanic activity on the Moon, flooded some – but not all – of the major impact basins some 100 Ma after impact basin formation (**Figure 8**). The ages of large mare basalt samples dated radiometrically range from 3.9 to 3.2 Ga. However, the onset of basaltic volcanism appears to be earlier; an age of 4.2 Ga has been reported for a basalt clast in a highland breccia (Taylor et al., 1983). Furthermore, data from the recent GRAIL mission identified large-scale subsurface linear gravity anomalies (Andrews-Hanna et al., 2013). These anomalies are interpreted as intrusive dikes formed before the early Nectarian (~3.8 Ga). In addition to the

possible identification of early volcanism, the structures are thought to result from a global expansion with a lunar radius increase of 0.6–4.8 km. It is however possible that these structures have been formed already during the solidification phase of the magma ocean. Crater counting methods indicate basalts in some unsampled areas of the Procellarum basin are as young as 1.3 Ga (Hiesinger et al., 2000). Such a long-standing volcanic activity can, for instance, be explained by the thermal blanketing effect of the regolith layer (Ziethe et al., 2009).

There is geochemical evidence of a deep origin for the mare basalts having relatively primitive compositions (Hess, 2000). This has often been cited as evidence for deep remelting of the lunar mantle. Furthermore, the TiO_2 content decreases with increasing depth and with increasing age (Basaltic Volcanism Study Project 1981; Head and Hiesinger, 1999), suggesting that the mare basalt source region moves deeper with increasing time. This observation has been confirmed with thermal evolution models using 2-D and 3-D mantle convection (Laneuville et al., 2013; Spohn et al., 2001). The results show a melt zone freezing from above as heat is removed through the growing lithosphere (**Figure 9(b)**) The freezing of the melt zone from above suggests that the magma source region moves to greater depths with time.

The time delay between mare formation and mare fill of about 100 Ma is not well understood. This time delay may be due to the time necessary for the melt to reach the surface after the impact since some time is required for a magma diapir or dike to penetrate through the lithosphere. Furthermore, ascending mantle diapirs likely stall at a basal crustal neutral buoyancy zone (Head and Hiesinger, 1999) before reservoir overpressurization propagates dikes to the surface. Alternatively, it has been suggested that the time delay is the consequence of a chemically stratified mantle following magma ocean differentiation and crystallization (Alley and Parmentier, 1998; Hess and Parmentier, 1995; Zhang et al., 2013). In the presence of a stabilizing compositional density gradient, the onset of thermal convection (due to heating of the interior, the thermal buoyancy can increase with time and overcome the stabilizing compositional density gradient) and thus the volcanic activity will be delayed if the model is started from a nonconvecting state (Alley and Parmentier, 1998). However, if it is assumed that the onset of convection was delayed until tens of Ma after the formation of the maria, the observed volcanic activity prior to the period of mare fill will be left unexplained.

Another open issue of the volcanic activity on the Moon is the observation that the mare basalts are mainly located on the nearside, the side facing the Earth (**Figure 9**). Thus, like Mars, the Moon shows a hemispheric asymmetry that is also reflected in a variation in the crustal thickness: the nearside with most of the mare basalts shows a significantly thinner crust in comparison to the crust on the farside. This was first inferred from the observed 2 km offset between the Moon's center of mass and center of figure roughly along the Earth–Moon axis (Kaula et al., 1972; see **Figure 8(b)**). The nearside–farside dichotomy of crustal thickness has been confirmed from Clementine and GRAIL data (Nozette et al., 1994; Wieczorek et al., 2013). One explanation for the existence of mare basalts in the thinner crust of the nearside is that the hydrostatic pressure of the mare source controls the eruption of mare basalts. Assuming that the maximum depth of the mare source was globally uniform, then mare basalts would only be able to erupt at the surface below a critical elevation. Thus, the higher elevations of the

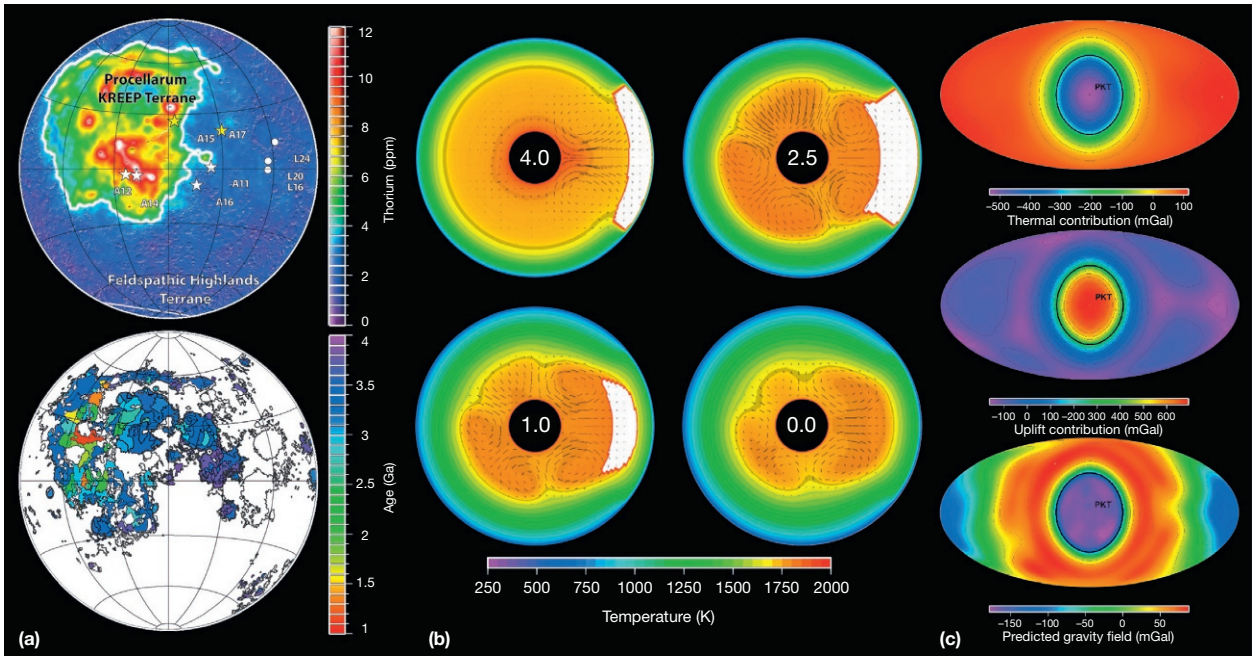

Figure 9 (a) Surface thorium concentration on the nearside (Lawrence et al., 2003): (top) the PKT region outlined in white and (bottom) mare basalt ages from Hiesinger et al. (2003). (b) Evolution of mantle temperature at four different times in Ga for a model with the KREEP layer located below the crust (white: partial melting region). (c) Contribution of thermal anomaly (top) and surface uplift (middle) to the present-day gravity anomaly over the PKT region under the assumption of a strengthless lithosphere (bottom). Reproduced from Laneuville M, Wieczorek M, Breuer D, and Tosi N (2013) Asymmetric thermal evolution of the Moon. *Journal of Geophysical Research* 118: 1435–1452. http://dx.doi.org/10.1002/jgre.20103.

lunar farside could have prevented farside magmas from reaching the surface due to their lack of the necessary pressure in their source. This scenario might, however, be a bit simplistic since the South Pole–Aitken basin has the lowest elevations on the Moon but mare flows in this basin are volumetrically insignificant when compared to the nearside basins.

It has been suggested that the basic lunar asymmetry was established during the magma ocean stage (Loper and Werner, 2000; Ohtake et al., 2012; Warren and Wasson, 1979) since the dynamically unstable configuration of the fractionated magma ocean might result in a large-scale overturn event (Hess and Parmentier, 1995). In that event, part of the KREEP layer is carried away together with the dense ilmenite layer. The large-scale downwelling eventually focused on the nearside would recycle the evolved KREEP-rich material into the deeper mantle providing a heat source for subsequent internal remelting on the nearside (Parmentier et al., 2002; see **Figure 10**). For a large-scale downwelling to develop, the viscosity of the dense layer needs to be significantly lower than the viscosity of the mantle below. Such scenario is difficult to obtain as this layer is expected to be rich in clinopyroxene while the underlying mantle may contain significant amounts of olivine. The latter being more deformable at the same conditions, the ilmenite-enriched layer may be more viscous than an underlying, more olivine-rich mantle at the same temperature (Elkins-Tanton et al., 2002). Alternatively, a large single upwelling may have evolved after the overturn (Zhang et al., 2013; Zhong et al., 2000); the dense ilmenite cumulates together with KREEP are distributed homogeneously atop the CMB but become thermally unstable with time to generate a single upwelling and thus generate the mare basalts (**Figure 10**). To produce a single upwelling, either a small core of less than 300 km (Zhong et al., 2000) – smaller than assumed from seismic observations (Garcia et al., 2011; Weber et al., 2011) – or a low activation energy (Zhang et al., 2013) is required. In addition, the timing, lateral extent, and even existence of the postulated overturn event are not well constrained.

Based on recent gamma-ray data from the Lunar Prospector, it has been realized that the crustal dichotomy is in fact more restricted (Lawrence et al., 1998, 2003). About 60% of the Moon's mare basalts reside in the Procellarum KREEP Terrane (PKT) (Wieczorek and Phillips, 2000). This province is in addition a unique geochemical crustal province enriched in incompatible and heat-producing elements; however, the titanium-rich mare basalts lack the KREEP signature (**Figure 9**). The later finding argues against the scenario, suggesting the rise of KREEP and ilmenite-rich layer from the CMB to produce the mare basalts (de Vries et al., 2010; Parmentier et al., 2002; Stegman et al., 2003; Zhang et al., 2013; Zhong et al., 2000). Wieczorek and Phillips (2000) had argued for a different genetic relationship between the mare basalts and the PKT. Specifically, by distributing a layer of KREEP basalt inhomogeneously below the crust, their thermal, purely conductive model predicts that the lunar mantle should have partially melted only beneath this province. The eruption of mare basalts thus may be primarily controlled by the distribution of heat sources in the Moon. This finding has been recently confirmed with 2-D and 3-D convection models in which an enriched concentration of heat sources in the PKT crust and an otherwise homogeneous mantle have been considered (Laneuville et al., 2013; **Figure 9**). Their model further shows that such an enriched concentration of heat sources in the PKT crust has an influence down to the CMB and leaves a present-day temperature anomaly within the nearside mantle. The latter would predict moderate gravitational and topographic anomalies that are however not observed but may be masked by either crustal thinning or gravitational anomalies from dense material in the underlying mantle.

Paleomagnetic data, combined with radiometric ages of Apollo samples, suggest that a field of possibly 100 μT existed between 3.8 and 3.6 Ga ago (Cisowski and Fuller, 1986; Stephenson et al., 1975). Recent paleointensity measurements on selected lunar samples (e.g., Lawrence et al., 2008) have indicated that lunar rocks are poor magnetic recorders and many of the early estimates of the paleointensities should be considered with caution. The new data, however, suggest a core dynamo may have existed on the Moon from at least 4.2 to 3.2 Ga with a peak in intensity of more than 10 μT at around

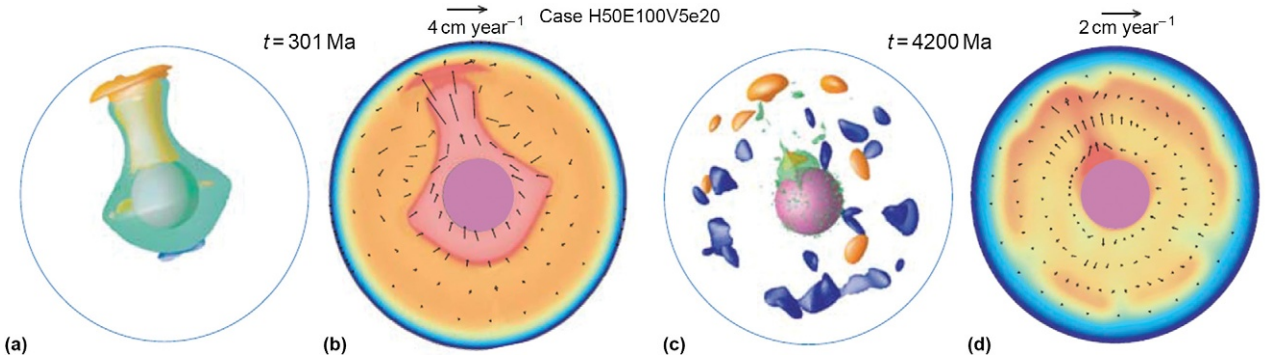

Figure 10 The 3-D thermochemical structures and 2-D cross sections for a model with a ilmenite-bearing cumulate (IBC) layer at the CMB that is enriched in radioactive elements and an activation energy of the mantle material of 100 kJ mol^{-1} (a and b) after 301 Ma and (c and d) at the present day is assumed. The arrows show the flow. Most of the 3-D thermal structures are plotted as isosurfaces of residual temperature with contour levels of −0.07 (blue) and 0.07 (orange) except for (a) that uses the contour level of −0.15 (blue) and 0.15 (orange). The residual temperature is the deviation from the azimuthally average temperature at given depth. The chemical structure is plotted as isosurfaces of compositional field (green). The surface and core–mantle boundary (CMB) are plotted as a blue curve and red spherical surface. Reproduced from Zhang N, Parmentier EM, and Liang Y (2013) A 3D numerical study of the thermal evolution of the Moon after cumulate mantle overturn: The importance of rheology and core solidification. *Journal of Geophysical Research* 118: 1789–1804. http://dx.doi.org/10.1029/jgre.20121.

3.7 Ga (Garrick-Bethell et al., 2009; Shea et al., 2012; Suavet et al., 2013; Tikoo et al., 2012). It should be noted though that due to the lack of data, it is uncertain whether the field ceased 3.2 Ga ago or whether the surface field was just weaker than 1 μT for a longer time after 3.2 Ga (Tikoo et al., 2012). Because the present magnetic field of the Moon is negligible, Runcorn (1975) had argued that the lunar rocks were magnetized at the time of their origin by a field of internal origin. The easiest explanation for such a field is the operation of a dynamo in an iron-rich lunar core. Some researchers doubt that an internal dynamo is required to explain the magnetization of the Moon and favor an alternative idea; the observed magnetic signature is suggested to be generated in association with large impacts during early history (Hide, 1972; Hood and Huang 1991; Hood and Vickery, 1984; Hood et al., 2001). In this model, magnetization should be concentrated diametrically opposite to major impact basins. Satellite observations from the Lunar Prospector mission show concentrations of crustal magnetization at the antipodes of some but not all of the large impact structures. Other models that might explain the younger magnetic signatures include mechanical stirring at the CMB from either precession (Dwyer et al., 2011) or changes in the lunar rotation rate from large impact events (Le Bars et al., 2011).

Assuming an internal origin of the lunar magnetic field, one must be aware that the paleomagnetic data show a gap of about 300 Ma in the remanent magnetization of the lunar rock. There exist two alternative explanations for this gap: (1) The remanent magnetization of older basaltic rock was destroyed by impact gardening and/or the volcanic activity during the first 300 Ma was very low, and (2) the internal field started about 300 Ma after core formation.

An early magnetic field has been suggested from thermal evolution models incorporating 2-D and 3-D convection with strongly temperature-dependent rheology (Konrad and Spohn, 1997; Laneuville et al., 2013; Spohn et al., 2001). These models show that a thermally driven dynamo might have been active from the beginning of the core formation and lasted a maximum of 500 My, that is, 4 Ga ago, if the core was superheated by about 200 K with respect to the mantle. These thermal evolution models, however, assume that at least the lower mantle is not chemically stratified.

A late onset of dynamo action takes into account the thermal and chemical consequences of the magma ocean (Stegman et al., 2003; Zhang et al., 2013). After crystallization of the magma ocean, dense ilmenite and pyroxene cumulates located just underneath the enriched KREEP layer sink to the deep lunar interior. This mixed enriched layer encircles the lunar core and insulates it from the rest of the mantle, trapping heat in the core and preventing the core from cooling convectively, and also from developing a dynamo. After a period of time, the radiogenic material within this 'thermal blanket' decays and heats the lower layer. Eventually, the material becomes more buoyant than its surroundings and rises toward the surface (**Figure 10**). With the removal of the thermal blanket, the core is then able to convect vigorously to cool itself, and this can produce a short-lived thermal dynamo. An essential element of the model is the timing. The length of time that it takes the thermal blanket to heat up and rise back toward the surface is broadly consistent with two important events in early lunar history – the eruption of the mare basalts onto the lunar surface and the magnetization of lunar rocks. Furthermore, the model may explain the phase of global expansion before the early Nectarian (~3.8 Ga) (Andrews-Hanna et al., 2013). Even so, the model has some shortcomings. First, the model would suggest the enrichment of KREEP in the mare basalts, which has not been observed (Lawrence et al., 1998, 2003); instead the enriched material is located adjacent to the basalts in the PKT. Second, for this blanketing layer to become thermally unstable so that core convection can be initiated, the density difference between the lower layer and the overlying mantle can only be a few tens of kg m^{-3} (deVries et al., 2010). The density of the ilmenite-rich layer is about 300 kg m^{-3} higher than the mantle below (Hess and Parmentier, 1995); thus, a mixture of the ilmenite-rich cumulate with the previously fractionated olivine–pyroxene cumulate is necessary for this process to work (Parmentier et al., 2002). The formation of such a layer is uncertain and it is even unlikely to sink due to unfavorable temperature and viscosity conditions (Elkins-Tanton et al., 2002). Furthermore, to obtain a single upwelling, a weak temperature-dependent Newtonian rheology with an effective activation energy of 100 kJ mol^{-1} is required (Zhang et al., 2013) – a value at the very low end even when considering that an effective activation energy for Newtonian rheology can be estimated by multiplying the actual activation energy of the non-Newtonian rheology by a prefactor of 0.3–0.6 (Christensen, 1984).

A recent interpretation of seismic data suggests that the core may have liquid outer and solid inner regions (Weber et al., 2011). Weber et al. (2011) estimated a 240 km radius solidified inner core within a core of 340 km radius. If true, this places strong constraints on the magnetic field generation in the Moon as a chemical dynamo may become a viable alternative – a possibility that has been neglected in most previous models. In case an inner core has grown during the lunar evolution, it needs to be explained why a dynamo has stopped about 3.2 Ga ago (or at least at the present day) although chemical convection is very efficient for the magnetic field generation (Braginsky, 1964; Stevenson et al., 1983). In addition, as a consequence of the low pressure range in the Moon's core, for a sulfur content higher than about 8 wt%, iron snow (see **Section 10.08.5.2.1**) is a likely mechanism for core solidification as it has been already suggested for Ganymede (e.g., Hauck et al., 2006), Mars (Stewart et al., 2007), and Mercury (Chen et al., 2008).

Recent studies suggest that water is more abundant in the lunar interior than previously thought (e.g., Grimm, 2013; Klima et al., 2013; McCubbin et al., 2011; Saal et al., 2008). Its distribution in the interior is possibly inhomogeneous as a consequence of the solidification of the magma ocean (Elkins-Tanton and Grove, 2011; McCubbin et al., 2011). In any case, the observation of interior water may have profound implications on the thermochemical evolution of the Moon as water even in small concentrations is known to have a strong effect on mantle rheology, with a viscosity reduction of more than a factor of 100 between water-saturated and completely dry material (e.g., Hirth and Kohlstedt, 1996; Mei and Kohlstedt, 2000). So far, most models have considered a dry rheology and the associated temperature profiles are generally consistent with the deep mantle temperatures suggested from seismic and gravitational inversions (e.g., Gagnepain-Beyneix et al., 2006; Khan et al., 2007) and electric conductivity studies

(Grimm, 2013; Hood et al., 1982). In general, a wet rheology predicts more efficient cooling, lower present-day mantle temperatures, and an earlier cessation of volcanism. This on the other hand would also suggest a higher sulfur concentration in the core to explain either an entirely fluid core or a solid inner core of 240 km (Weber et al., 2011).

10.08.6.4 Mars

A fundamental problem in the evolution of Mars is the timing and the origin of the crustal dichotomy. The southern highlands and northern lowlands of Mars differ markedly in average elevation (Smith et al., 1999a,b) and crustal thickness (Neumann et al., 2004; Zuber et al., 2000). Although it is generally accepted that this crustal dichotomy is one of oldest features on Mars, the exact timing of the dichotomy formation, which has implications for the formation mechanism, is strongly debated. Early studies on faulting and other tectonic features at the crustal dichotomy boundary suggested a Late Noachian/Early Hesperian (3.7 Ga) formation for the dichotomy (McGill and Dimitriou, 1990). Most recent studies suggest an Early Noachian or earlier (>3.9 Ga) formation time for the dichotomy (Frey et al., 2002; Nimmo and Tanaka, 2005). One argument for this early crustal formation is the finding of quasi-circular depressions in the northern lowlands (Frey et al., 2002). They are interpreted as buried impact craters and are suggestive that the basement of northern lowlands formed during the Early Noachian and may be even older than the visible highlands. Solomon et al. (2005) even suggested an early crustal formation, including the dichotomy structure, as early as the first 50 Ma after the solar system formation. Lines of evidence include the isotopic anomalies in Martian meteorites (Borg et al., 1997; Brandon et al., 2000; Chen and Wasserburg, 1986; Halliday et al., 2001; Harper et al., 1995) that indicate an early differentiation event of the mantle about 4.5 Ga ago. The SNC meteorite isotope data further suggest insignificant reservoir mixing thereafter (Jagoutz, 1991).

The origin of the crustal dichotomy has variously been related to external (Frey and Schultz, 1988; Wilhelms and Squyres, 1984) and internal processes (Wise et al., 1979), but none of the proposed formation mechanisms has been fully convincing in part due to the uncertainty in the timing of the dichotomy formation. For the external processes, one impact (Wilhelms and Squyres, 1984) or several large impacts (Frey and Schultz, 1988) have been suggested as an explanation of the crustal dichotomy. This idea has recently been revived in a series of articles explaining the observed elliptical shape of the lowlands (Andrews-Hanna et al., 2008; Marinova et al., 2008; Nimmo et al., 2008). However, an endogenic origin of the dichotomy cannot be ruled out. For an endogenic origin of the dichotomy, four different mechanisms have been proposed that are associated with (1) the evolution of an early magma ocean (Elkins-Tanton et al., 2003; Hess and Parmentier, 2001), (2) an episode of degree-one mantle convection (Ke and Solomatov, 2006; Keller and Tackley, 2009; Schubert and Lingenfelter, 1973; Wise et al., 1979; Zhong and Zuber, 2001), (3) a thermal anomaly following a giant impact in the southern hemisphere (Golabek et al., 2011; Reese and Solomatov, 2006; Reese et al., 2010), and (4) an early phase of plate tectonics (Sleep, 1994).

The crustal dichotomy may have arisen from a heterogeneous evolution of a magma ocean or the crystallization of a magma ocean may have led to gravitationally unstable layering (a similar suggestion has been proposed for the Moon, which also exhibits a hemispheric crustal thickness variation; see **Section 10.08.6.3**), as the late-stage silicates that crystallized at shallow mantle depths were denser than earlier cumulates that crystallized near the base of the magma layer. A potential long-wavelength overturn of an unstable mantle may have thickened the crust over the downwelling region and thinned the crust elsewhere (Hess and Parmentier, 2001) although this fails to explain the sharpness of the dichotomy or the relative uniformity of the crustal thickness in the southern highlands.

An episode of long-wavelength mantle convection after the solidification of an early magma ocean has been suggested for a layered mantle viscosity structure with a viscosity jump of more than a factor of 25 in the midmantle (Roberts and Zhong, 2006; Zhong and Zuber, 2001) or alternatively a midmantle viscosity jump linked to the Martian mineralogical transition zone below 1000 km depth (Keller and Tackley, 2009). Another situation that yields degree-1 mantle convection is the possible existence of the endothermic spinel-to-perovskite just above the Martian core (Harder and Christensen, 1996). The time required to develop degree-1 mantle convection ranges from 100 Ma to several hundred Ma and is too slow to satisfy the geochemical constraints on the timing of the dichotomy formation. Additionally, these models result in continuous magmatic resurfacing of the southern hemisphere, thereby destroying the initially dichotomous crustal structure in the long term. Ke and Solomatov (2006) on the hand suggested a large, transient upwelling that arose from a hot bottom thermal boundary layer generated by the initially hot Martian core. A superheated core relative to the mantle of 1000 K is required to form one large plume. Its development can be very fast, on the order of 10–1000 My depending on the value of mantle viscosity. None of these models explains the sharpness of the dichotomy nor the relative uniformity of the crustal thickness in the southern hemisphere.

A hybrid model of exogenic and endogenic origin has been proposed by Reese et al. (2010) and Golabek et al. (2011). A giant impact event during the late stage of planetary formation is the source of the southern highland crust. In a second stage, the extraction of excess heat by vigorous mantle convection on the impacted hemisphere leads to massive magmatism, forming a distinct Tharsis-like volcanic region (Golabek et al., 2011). The location of the volcanic region is, however, inconsistent with the observed position of Tharsis at the dichotomy boundary. A solution to that problem might be the relative rotation of the entire lithosphere relative to the underlying mantle. Taking the presence of a hemispheric lithospheric keel into account that represents a depleted mantle reservoir, Šrámek and Zhong (2012) demonstrated that a stiff keel can induce a rotation, until an upwelling is stabilized near the edge of the keel. This edge corresponds to the dichotomy boundary, thus accounting for the location of the Tharsis rise. Sleep (1994) proposed that the smooth northern lowlands and the Tharsis volcanoes were produced as an ocean floor and an island arc volcanic chain similar to these features on Earth. More recently, the magnetic lineation patterns on parts of the

southern highlands detected by MGS have been interpreted to be the result of plate divergence (Connerney et al., 1999, 2005). The dating of the magnetic anomalies led the authors to suggest that the potential early plate tectonic regime lasted about 500 Ma. However, there is no consistent geologic evidence for such a regime on Mars (Nimmo and Tanaka, 2005).

The proposed scenarios for the formation of the crustal dichotomy have different implications for the thermal evolution of Mars, in particular for the early evolution. At the present stage and most likely during the last 4 Ga, Mars is and was in the stagnant lid regime with a stable plate on top of the convecting mantle. The first few hundred million years, however, is an uncertain epoch and it is unknown whether the planet was in a phase of plate tectonics that later changed to one-plate tectonics or whether the planet never changed its heat transport mechanism and always was in the stagnant lid regime.

The existence of a brief episode of plate tectonics has important consequences for the thermal evolution of the planet. Assuming stagnant lid convection throughout the entire evolution of Mars, most models show a continuously cooling interior. In contrast to the stagnant lid convection throughout the entire evolution, an early plate tectonic regime suggests a rapidly cooling interior during the first few hundred million years. As soon as plate tectonics stops, the heat transport becomes inefficient and the interior heats up until the temperature again decreases slowly to its present value that does not differ significantly to the temperature of the models with stagnant lid convection throughout the entire evolution assuming the same reference viscosity (**Figure 11**). The temperature increase also suggests a decrease in the thickness of the elastic lithosphere after cessation of plate tectonics and during a long

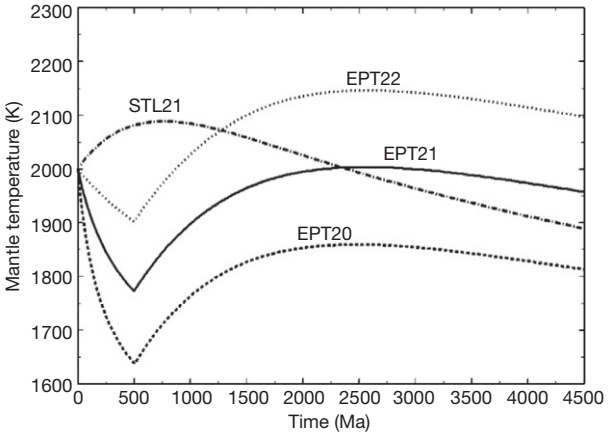

Figure 11 Mantle temperature as a function of time for three models with early plate tectonics. After 500 Ma, plate tectonic ceases and stagnant lid convection sets in. Model EPT20 has a reference viscosity of 10^{20} Pa s (dashed line), model EPT21 a reference viscosity of 10^{21} Pa s (solid line), and model EPT22 a reference viscosity of 10^{22} Pa s (dotted line). Also shown is the temperature for the stagnant lid convection model STL21 with a reference viscosity of 10^{21} Pa s (dash-dotted line). This model assumes stagnant lid convection throughout the entire evolution of Mars. Reproduced from Breuer D and Spohn T (2003) Early plate tectonics versus single-plate tectonics: Evidence from the magnetic field history and crust evolution. *Journal of Geophysical Research: Planets* 108(E7): 5072. http://dx.doi.org/10.1029/20002JE001999.

period of Martian evolution. Such a trend, however, has not been observed (McGovern et al., 2004; Zuber et al., 2000).

The elastic lithosphere thicknesses, which were derived from an analysis of the gravity and topography data, suggest a rapid growth during the Noachian and a more modest subsequent growth (McGovern et al., 2004; Zuber et al., 2000). This trend is in general consistent with the thermal evolution models (Breuer and Spohn, 2003, 2006; Breuer et al., 1993; Grott and Breuer, 2008; Ruiz et al., 2011; Schubert et al., 1992; Spohn et al., 1998), which show a rapid growth of the elastic lithosphere (defined by an isotherm of 1050 K) from a few kilometers to more than 100 km during the first few hundred million years and later a slower growth to values of 130–200 km. A present-day value of the elastic thickness has been derived using radar sounding data obtained by SHARAD, the shallow radar onboard the Mars Reconnaissance Orbiter; Phillips et al. (2008) found that the Martian lithosphere is extremely stiff and T_e is larger than 300 km at the north pole today. This is almost twice as large as previously estimated from thermal evolution models and contradicts the best fit elastic thickness derived from flexure studies of the south polar load with $T_e = 140$ km, although any value greater than 102 km can fit the observations (Wieczorek, 2008). The large present-day elastic lithosphere can be explained if the planet's bulk heat production elements are about 25–50% subchondritic or – which is more likely – the large elastic thicknesses in excess of 300 km are not representative for the bulk of the planet and T_e possibly shows a large degree of spatial heterogeneity (Grott and Breuer, 2009; Ruiz et al., 2011; **Figure 12**).

In addition, the estimated small values of the effective elastic lithosphere thickness of less than 16 km (Grott et al., 2005, 2007; McGovern et al., 2004; Zuber et al., 2000) are difficult to explain unless the observed features are Early Noachian in age (more than 4 Ga; Hartmann and Neukum, 2001). In particular, the analysis of rift valley topography in the Thaumasia region (Grott et al., 2005, 2007) where the formation of the examined rift zones has actually been dated at the transition of the Noachian to the Hesperian ($\sim$1 Gy after accretion) suggests an effective elastic lithosphere thickness of about 12 km, which is inconsistent with the present models showing a rapid growth of the elastic lithosphere to more than 100 km during the first few hundred million years.

An alternative explanation for the observed rapid growth of the elastic lithosphere thickness is given by the effect of rheological layering of an enriched and low-conductivity primordial crust on the thermal evolution (Grott and Breuer, 2008, 2009; Schumacher and Breuer, 2006). Thus, the rapid growth of the elastic lithosphere can be the consequence of a change of the mechanical state of the crust–mantle interface, with a low elastic thickness corresponding to mechanical decoupling and high elastic thickness corresponding to mechanical coupling of the crust and mantle. Decoupling in the young and warm lithosphere is caused by the presence of an incompetent layer in the lower crust that later disappears due to lithospheric cooling. In order for an incompetent layer to exist, a weak crustal rheology is required (Grott and Breuer, 2008, 2010), and given the absence of large-scale felsic deposits (e.g., Nimmo and Tanaka, 2005), it seems likely that water is responsible for rheological weakening. Furthermore, small elastic

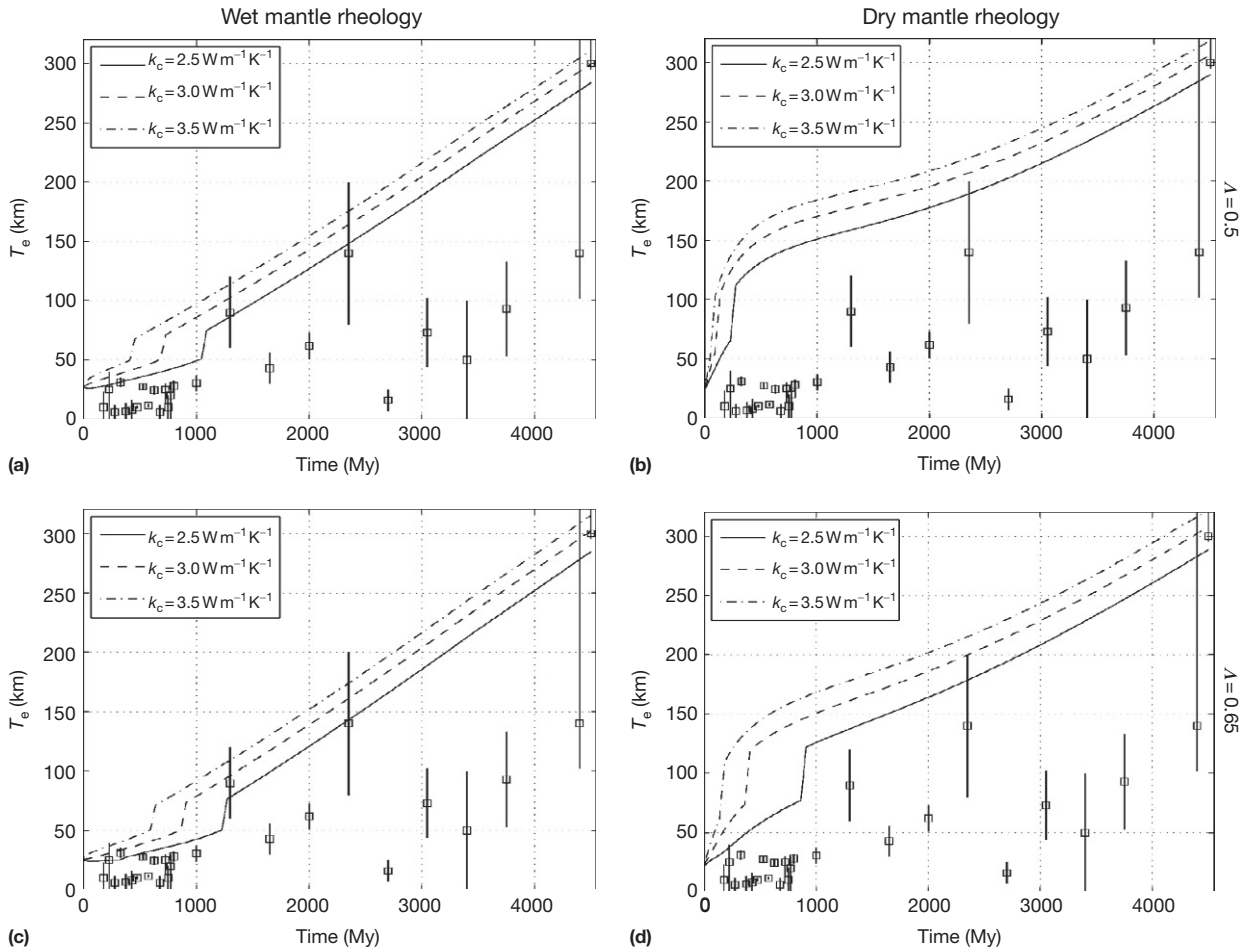

Figure 12 The elastic lithosphere thickness T_e as a function of time for thermal evolution models with (a) and (c) a wet mantle rheology and (b) and (d) a dry mantle rheology, varying the crustal thermal conductivity k_c. The bulk concentration of heat-producing elements has been reduced with respect to the reference model (Wänke and Dreibus, 1994) such that today's elastic thickness is ~300 km (Phillips et al., 2008). Remaining radioactive elements have concentrations of (a) $\varphi = 0.5$, (b) $\varphi = 0.75$, (c) $\varphi = 0.65$, and (d) $\varphi = 1$ with respect to the reference model. Heat-producing elements are enriched in the crust and $\Lambda = 0.5$ and 0.65 in (a)–(b) and (c)–(d), respectively. Elastic thickness estimates from the literature (Belleguic et al., 2005; Grott et al., 2005, 2007; Hoogenboom and Smrekar, 2006; Kronberg et al., 2007; McGovern et al., 2004; Phillips et al., 2008; Schultz and Watters, 2001; Wieczorek, 2008) are also given. Reproduced from Grott M and Breuer D (2009) Implications of large elastic thicknesses for the composition and current thermal state of Mars. *Icarus* 201(2): 540–548.

thicknesses require relatively thin thermal boundary layers in the upper mantle, indicating that mantle convection was active and vigorous during this time period. A vigorous convecting mantle is, however, more difficult to reconcile with the sustainment of early reservoirs in the Marian mantle to explain the SNC isotope characteristic (Jagoutz, 1991; see also discussion later in the text). In fact, thin thermal boundary layers also require low mantle viscosities, indicating that the convecting mantle is best described by a wet or only partially dehydrated rheology (**Figure 12**). A wet crust is consistent with an early, deep-seated global-scale hydrologic system on Mars (Andrews-Hanna et al., 2007; Parmentier and Zuber, 2007), which would be conducive to a wet crustal rheology. The water content of the Martian mantle, however, is strongly debated. The SNC meteorites are one of the few constraints available to estimate the amount of water in the Martian mantle. The bulk water content of the SNC meteorites is relatively small and ranges from 50 to 150 ppm (Leshin et al., 1996), indicating low mantle water contents in the source regions of the SNC meteorites between only 5 and 15 ppm (Filiberto and Treiman, 2009). However, it has been argued that magmatic degassing could be responsible for the low bulk water content in the SNC meteorites (Balta and McSween, 2013; McSween et al., 2001), and the water content of the Martian mantle could be considerably larger with values between 55 and 220 ppm H_2O (McCubbin et al., 2010, 2012b), values similar to that of the Earth's mantle.

Crustal formation provides an important link between mantle and atmospheric reservoirs (see review in Grott et al., 2013) as volcanic outgassing is one of the main sources of volatiles for the Martian atmosphere and it depletes the mantle with time in these elements. Water behaves similar to other moderately incompatible elements and will preferably move to the liquid phase upon partial melting. Thus, it will be extracted from the mantle during the crustal formation process. Part of this water will then be outgassed into the atmosphere through

extrusive volcanism. Based on thermochemical models, the water depletion in the mantle ranges between 50% and 80% (Fraeman and Korenaga, 2010; Grott et al., 2011b; Morschhauser et al., 2011), with 50% being the preferred model that can explain various observables on Mars (Grott et al., 2011b). The latter models imply that the mantle is homogeneously depleted. Models that also consider compositional variation due to melting, however, suggest a depleted upper mantle (depleted in crustal compounds and volatiles) and a lower primordial mantle that still contains a substantial amount of water (Plesa and Breuer, 2014; **Figure 14**) as suggested by a recent analysis of the SNC meteorites (Balta and McSween, 2013).

Mars has been volcanically active throughout its history. In fact, the recent detection of young lava flows (< 100 Ma) suggests that the planet has been volcanically active up to the recent past (Hartmann et al., 1999). A continuous decline of the volcanic activity has been suggested since the Noachian. Martian volcanism and stratigraphy have been reviewed by Greeley and Spudis (1981), Tanaka et al. (1992), and Mouginis-Mark et al. (1992). The time of crustal formation has been constrained using isotope data gathered from SNC meteorites (see Halliday et al., 2001, for a recent review) and surface morphological data on volcanic extrusions. A study of the Nd mass balance in Martian meteorites (Norman, 2002) proposes a two-stage formation of the Martian crust with 20–30 km crust formed early, possibly simultaneously with core formation, and 45–75 km thereafter from depleted mantle sources. The exact timing of the second stage, however, cannot be constrained with the geochemical data.

The present thickness of the Martian crust is also not very well known and estimates of the average thickness vary between 40 and 150 km. The upper value has been derived from models of the interior structure of Mars based on the moment of inertia factor and the chemistry of the SNC meteorites (Sohl and Spohn, 1997; Sohl et al., 2005) and the lower value from a Bouguer inversion of the gravity and topography data assuming Airy isostasy (or a crust density that is everywhere the same) and further assuming that the floor of the Hellas impact basin defines the minimum crustal thickness (Zuber et al., 2000). Combining the different constraints on the crustal thickness, a globally averaged crustal thickness of 50 ± 12 km (Wieczorek and Zuber, 2004) seems likely (see **Chapters 10.02** and **10.05** for more details) in agreement with a crustal thickness recently estimated from geochemical measurements (Humayun et al., 2013).

The thermochemical evolution models that include crustal growth with either parameterized (Breuer and Spohn, 2003, 2006; Breuer et al., 1993; Fraeman and Korenaga, 2010; Grott et al., 2011b; Hauck and Phillips, 2002; Morschhauser et al., 2011; Schubert et al., 1992; Spohn, 1991) or 2-D and 3-D convection models (Golabek et al., 2011; Keller and Tackley, 2009; Li and Kiefer, 2007; Ogawa and Yanagisawa, 2011, 2012; Ruedas et al., 2013a,b; Schumacher and Breuer, 2006; Šrámek and Zhong, 2012) usually predict that most of the crust formed in the first billion years. These models in general confirm the observation of a continuous decline of global volcanism and crustal growth since the Noachian. Furthermore, the initial temperature distribution in the Martian interior and the viscosity structure of the Martian mantle were identified as the key parameters influencing mantle melting and the evolution of the Martian crust – thus the thickness of the crust at the end of the thermal evolution. In contrast, models with early plate tectonics in Mars show an early efficient cooling during the phase of plate tectonics that will either frustrate later crustal production and may not explain, for example, the northern volcanic plains in the Early Hesperian or show a crustal growth rate with a late peak (about 2 Ga) that is not observed (Breuer and Spohn, 2003).

The strict assumption that most of the crust is produced during the first few hundred million years (Nimmo and Tanaka, 2005; Solomon et al., 2005) places a strong constraint on thermal evolution models that assume stagnant lid convection throughout the entire evolution. Hauck and Phillips (2002) argued that only a wet mantle with an initial mantle temperature of about 1700 K can explain this observation. In contrast to these findings, Breuer and Spohn (2006) showed that models with a dry Martian mantle are also consistent with the crustal evolution if the initial mantle temperature after core formation is high enough and if a primordial crust has been formed during core formation. Irrespective of mantle viscosity, the present-day mantle cooling rates are 40–50 KGy^{-1}. These values are in general agreement with geochemical observations from which cooling rates of 30–40 KGy^{-1} have been derived (Baratoux et al., 2011). The ambiguity of a wet versus dry Martian mantle has recently been investigated on the basis of elastic thickness estimates, which indicate that a dry mantle rheology is incompatible with the low elastic thicknesses suggested for the Noachian and Early Hesperian periods (Grott and Breuer, 2008, 2010).

The observed recent volcanic activity in the large volcanic provinces, Tharsis and Elysium (Berman and Hartmann, 2002; Hartmann et al., 1999; Neukum et al., 2004), places another important constraint on the thermochemical evolution. In these regions, the volcanic activity was most likely active for a few billion years although the bulk of the volcanic provinces was present since the Noachian (Banerdt and Golombek, 2000; Phillips et al., 2001b). Thermochemical evolution models (Breuer and Spohn, 2003, 2006; Fraeman and Korenaga, 2010; Hauck and Phillips, 2002) suggest that crustal formation ceased 1–3 billion years ago based on the fact that the average mantle temperature fell below the mantle solidus. Among the models assuming a wet mantle rheology, the crustal production ceases faster due to more efficient cooling. To obtain long-standing melt production, in particular, an insulating crust and the formation of a depleted upper mantle layer help to prolong the volcanic activity even with a weak mantle rheology (Morschhauser et al., 2011; Plesa et al., 2014). In particular, the influence of an insulating crust to prolong the volcanic activity has been already shown for the Moon (Ziethe et al., 2009) and Mercury (Grott et al., 2011a; Tosi et al., 2013). Note, however, that parameterized models cannot account for lateral variations in crustal production, and fully 2-D or 3-D convection models need to be applied in order to resolve young, localized volcanism.

The existence of long-standing volcanism in Tharsis and Elysium up to recent times could be explained with stable and long-standing plumes that have a higher temperature than the average mantle. As both Tharsis and Elysium are located near or at the dichotomy boundary, a dynamic link

between these two features has been suggested (Golabek et al., 2011; Šrámek and Zhong, 2010, 2012; Wenzel et al., 2004; Zhong, 2009). Possible mechanisms to generate stable and long-standing plumes may be due to a deep phase transition (Breuer et al., 1998; Harder, 2000; Harder and Christensen, 1996; Weinstein, 1995). In particular, the endothermic spinel-to-perovskite phase transition that might be located close to the CMB (see also **Chapter 10.02**) helps to stabilize the plumes and reduces their number to one or two upwellings, although the long timescale necessary to form a single upwelling in most models is inconsistent with an early formation of either the dichotomy or the volcanic provinces (Michel and Forni, 2011; Roberts and Zhong, 2006). Another efficient way to induce low-degree convection has been suggested by a pronounced rheological stratification with an increase of the viscosity with depth (Golabek et al., 2011; Keller and Tackley, 2009; Roberts and Zhong, 2006; Šrámek and Zhong, 2010; Zhong, 2009). Presently, it is uncertain whether such pronounced viscosity stratification exists on Mars. A detailed model by Ruedas et al. (2013a,b) in which the viscosity depends on temperature, pressure, melt, and mineralogy does not obtain low-degree convection during the thermal evolution.

Another mechanism to generate long-standing plumes – although not just a single one – has been proposed assuming chemical layering with either a variable mantle thermal conductivity (Schott et al., 2001), a low conducting crust (Plesa and Breuer, 2014), or the presence of the crustal dichotomy (Wenzel et al., 2004). For these mechanisms, the existence of a chemically layered mantle is required to occur early in the evolution due to fractionation of a magma ocean (Wenzel et al., 2004) or as the consequence of crustal formation due to the formation of a depleted upper mantle layer, which does not remix with the remaining undepleted lower mantle (Plesa and Breuer, 2014; Schott et al., 2001). Furthermore, an alternative mechanism has been proposed by Schumacher and Breuer (2006) that may also work in addition to the previous scenarios. Once the main structure of the volcanic provinces has been built up, the lateral thickness variations of the low-conductivity crust allow the continuous generation of melt underneath these thickened regions and may explain the long-standing and recent volcanism in Tharsis and Elysium. It has been suggested that the crust underneath Tharsis is about 20–40 km thicker than in its surroundings (Neumann et al., 2004).

Most thermal evolution models implicitly assume the Martian mantle to be homogeneous, but the existence of distinct geochemical reservoirs is suggested by isotopic anomalies in the Martian meteorites (Borg et al., 1997; Brandon et al., 2000; Chen and Wasserburg, 1986; Halliday et al., 2001; Harper et al., 1995). These data indicate an early mantle differentiation event about 4.5 Ga ago and insignificant reservoir mixing thereafter. One possible mechanism to form distinct and separate geochemical reservoirs is magma ocean solidification by fractional crystallization, which likely results in an unstable density stratification in the Martian mantle. Late-stage silicates that crystallize at shallow depths are denser than earlier cumulates that crystallize near the base of the magma ocean – a situation prone for vigorous mantle overturn (Elkins-Tanton et al., 2003, 2005; Hess and Parmentier, 2001).

The mantle overturn is assumed to occur during the first 100 Ma (Debaille et al., 2007, 2009; Elkins-Tanton et al., 2003, 2005a,b). As a consequence of the overturn, the dense surface material sinks to the CMB while the light material from the CMB rises to the surface – a stable chemical-layered mantle develops (**Figure 13**), which is in its composition in particular in the midmantle laterally heterogeneous (Elkins-Tanton et al., 2005; Zaranek and Parmentier, 2004). It is further assumed that, during the vigorous overturn, rising upwellings can melt by adiabatic decompression and produce an early crust. The residual mantle of this process is, for instance, associated with the source region of the nakhlites (Debaille et al., 2009). The chemical layering after the overturn suppresses subsequent thermally driven convection and early-formed reservoirs are preserved throughout the entire planet's history.

Although such a process would form distinct geochemical reservoirs, models of the interior evolution after mantle overturn indicate that subsequent thermal convection – if existent at all – is very weak. This contradicts the small elastic lithosphere thicknesses derived for the Noachian period, which require the lithosphere to be warm and the upper thermal boundary layer to be thin (Grott and Breuer, 2008). Furthermore, different reservoirs remain dynamically strictly separated, because the density differences between different layers are large (Tosi et al., 2013b; Plesa et al., 2014). A potential reservoir in the deep mantle would have no surface expression and thereby would remain 'invisible,' contrary to observations. Therefore, alternative explanations for the early formation of reservoirs that did not mix significantly during the subsequent evolution are needed. One such model includes the rapid formation of a harzburgite layer (Ogawa and Yanagisawa, 2011, 2012; Plesa and Breuer, 2014; Schott et al., 2001) by early crustal formation, which would be less dense than the primordial mantle and would remain stable, while the lower mantle layer consists of compositionally denser materials not depleted in the basaltic component – the larger the density contrast between depleted mantle and primordial mantle, the more stable is the layering (**Figure 14**). The stability of the layering is even enhanced as a consequence of dehydration and subsequent stiffening in case of a wet mantle (Plesa and Breuer, 2014). These two layers convect separately and hot plumes grow from the lower mantle layer making it thinner with time by erosion – its composition, however, remains almost primordial (**Figure 14**). The stiff and buoyant upper mantle layer thermally isolates the interior, and due to the associated slow cooling of the mantle, partial melting can exist for a substantial time period in the evolution. The longevity of volcanism is further enhanced by the low conducting crust with the upwellings in the depleted upper mantle layer being very stable (Plesa and Breuer, 2014). In the case of crustal recycling, another 'hidden' reservoir consisting of eclogitic material that is denser than the primitive mantle would accumulate at the CMB (Ogawa and Yanagisawa, 2011, 2012). Whether such a model can also explain the isotope characteristic of the SNC meteorites remains to be studied.

At present, Mars has no global dipole magnetic field, but regions of strongly magnetized ancient crust indicate that an internal field once existed, one of the most astonishing outcomes of the MGS mission (Acuña et al., 1998, 1999, 2001; Connerney et al., 1999). After the MGS Orbit Insertion in 1997

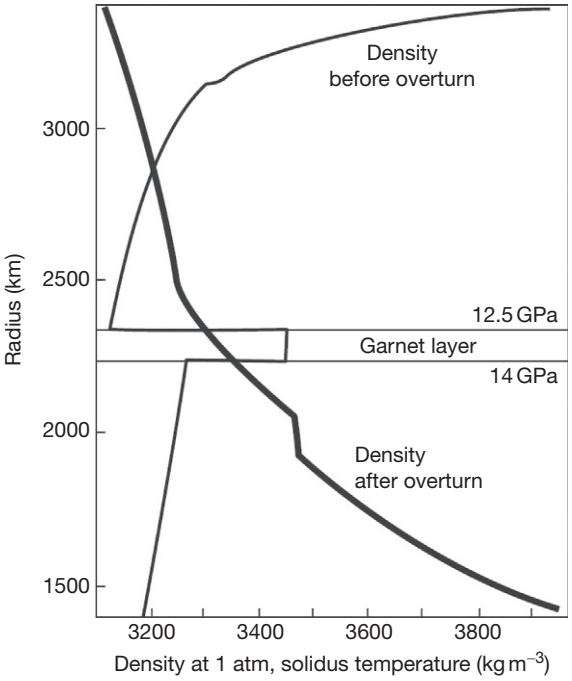

Figure 13 Preoverturn and postoverturn density profiles for a simple fractional crystallization model of a whole mantle Martian magma ocean showing the gravitational stability of the mantle after overturn and the existence of overlapping density gradients before overturn that result in lateral compositional and temperature heterogeneities in the overturned mantle. Figure 14 Formation of geochemical reservoirs in the Martian mantle. Depending on the assumed density contrast between primitive mantle and residual mantle (mantle material depleted in crustal components during the melting process), two to four distinct reservoirs may form early in the planetary evolution. Left panels show the concentration of radioactive elements in the crust and mantle for the two scenarios after 4.5 Ga. Reproduced from Plesa AC and Breuer D (2014) Partial melting in one-plate planets: Implications for thermo-chemical and atmospheric evolution. *Planetary and Space Science*, special issue 'Planetary evolution and life', 98: 50–65, http://dx.doi.org/10.1016/j.pss.2013.10.007.

and during the aerobraking phase and science-phasing orbit phase, it was possible to get magnetic measurements at periapses ranging from 85 to 170 km above Mars' surface. Connerney et al. (1999) (see also Acuña et al., 2001; Purucker et al., 2000) had discovered strongly magnetized regions in the crust, closely associated with the ancient, cratered terrain of the highlands in the southern hemisphere. There has been a great interest in the meaning of the spatial pattern of magnetization (Arkani-Hamed, 2004; Jurdy and Stefanick, 2004), including possible lineations (these crustal magnetizations even suggest reversals) that were believed to suggest an analogy to plate tectonics (Connerney et al., 1999, 2005), but other models favor thermal remanence acquired during the time these ancient rocks cooled in conjunction with dike intrusions (Nimmo, 2000). The inferred crustal magnetizations, which are up to $\sim$10–30 A m^{-1}, are an order of magnitude stronger than those of the Earth's continents (Arkani-Hamed and Dyment, 1996; Toft and Arkani-Hamed, 1992) and comparable in magnitude with the remanent magnetization of fresh extrusive basalt near the oceanic ridge axes of Earth (Bleil and Petersen, 1983). These magnetic anomalies indicate the existence of a strong ancient intrinsic Martian magnetic moment corresponding to a magnetic field strength of 0.1–10 times that of the Earth's at present (Mitchell et al., 1999, 2001; Ness et al., 1999).

There are several ways in which the Martian crust could have been magnetized. One of the most probable ways is thermoremanent magnetization (TRM). With TRM, the magnetization is produced when rock cools below a critical temperature (Curie temperature) in the presence of a magnetizing field. This is an effective mode for producing an intense remnant field. The magnitude of magnetization produced in the rock depends on the strength of the internal field, the mineralogy, and the magnetic microstructure. There is a trade-off between the concentration of magnetic carriers and the strength of the magnetic field: The lower the imposed magnetic field, the more magnetic carriers are required to explain an observed magnetization. Assuming an early Martian magnetic field similar to the present-day Earth field, the concentration of magnetic carriers might be comparable to the amount in extrusive basalt. Bearing in mind the possible reduction of the remnant magnetization through viscous decay and chemical alterations during this very long geologic time (the magnetization of the oceanic basalt decreases by a factor of 4–5 during the first 20 My, largely by chemical alterations (Bleil and Petersen, 1983)), the initial magnetization of the Martian source bodies must have been even stronger. However, there is ample evidence that the FeO content of the Martian mantle is about twice that of the Earth's mantle (Sanloup et al., 1999; Sohl and Spohn, 1997). Whether this high concentration of FeO translates to a high concentration of magnetic minerals depends on the oxidation state of the Martian mantle and lower parts of the crust. However, for a high concentration of magnetic minerals, the early magnetic field could have been smaller than that of the present Earth.

The timing of the dynamo places strong constraints on the thermal evolution of the planet. It has been proposed on the basis of the surface distribution of the magnetic anomalies that this magnetization event predated the formation of the Hellas and Argyre basins (Connerney et al., 1999; Lillis et al., 2013), roughly at the end of the Early Noachian (Head et al., 2001). The existence of an early magnetic field has been supported by the ancient Martian meteorite ALH84001, which shows a magnetization that was acquired at 4 Ga or even earlier (Weiss et al., 2002). However, the lack of an appreciable magnetization in two ancient areas on the highlands, the South Province and the Tempe Terra, further suggests that no strong dynamo existed in the first $\sim$100 My of Mars' history (Arkani-Hamed and Boutin, 2012). It has been alternatively suggested that the dynamo turned on after the giant impact craters formed, implying that the remnant magnetization of the crust was acquired later in Martian history (Schubert et al., 2000). This hypothesis is supported by the SNC meteorites with formation ages of 1.3 Ga to 180 Ma, which show a remnant magnetization consistent with a weak ancient surface field of a few hundred to a few thousand nanoteslas (Collinson, 1997; Rochette et al., 2001). This weak surface field may suggest a late onset or reactivation of a core dynamo that would have stopped operating before the present. However, it is also possible that the young Martian meteorites were magnetized by the older and strongly magnetized crustal rock (see Connerney et al., 2003, for a review).

The evidence of early dynamo action is supported by most thermal evolution models that consider the magnetic field history (e.g., Breuer and Spohn, 2003, 2006; Hauck and Phillips, 2002; Michel and Forni, 2011; Schubert and Spohn, 1990; Spohn et al., 1998; Williams and Nimmo, 2004). The models assume a thermally driven dynamo during the first few hundred million years as the consequence of the early rapid cooling if the core is superheated with respect to the mantle as a consequence of the rapid core formation process (**Figure 15**) – although these models are at variance with a later dynamo start after the first 100 My (Arkani-Hamed and Boutin, 2012). In the subsequent evolution, the core remains liquid with a heat flow below the critical value and, thus, no dynamo action

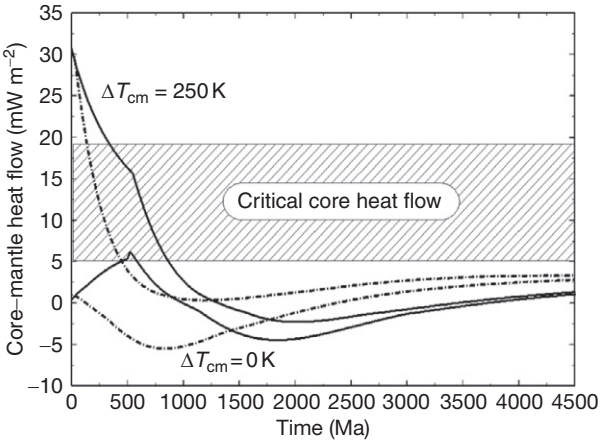

Figure 15 Core–mantle heat flow as a function of time for models with early plate tectonics (solid line) and models with stagnant lid convection throughout the entire evolution (dash-dotted line) with initial temperature differences across the CMB of ΔT_{cm} = 0 and 250 K. Reproduced from Breuer D and Spohn T (2003) Early plate tectonics versus single-plate tectonics: Evidence from the magnetic field history and crust evolution. *Journal of Geophysical Research: Planets* 108(E7): 5072. http://dx.doi.org/10.1029/20002JE001999.

until today. A totally molten core for the entire evolution is possible if the core contains at least ~5 wt% sulfur (Williams and Nimmo, 2004), although the more recent melting data of Fe–FeS by Stewart et al. (2007) suggest a sulfur threshold of at least 10% or even higher depending on the efficiency of cooling. A core sulfur abundance of 14.2 wt% is suggested for Mars from geochemical analysis of the SNC meteorites (Dreibus and Wänke, 1985; McSween, 1985). Assuming a sulfur content in the core below 10 wt%, inner core growth and consequently a chemical dynamo would be possible. Such a scenario, however, is at variance with the assumption of a brief, very early dynamo. If core solidification did take place on Mars, it likely would have generated a very long-lived dynamo (Schubert et al., 1992) unless the iron snow is the prevalent freezing mechanism in the Martian core as suggested by Stewart et al. (2007). For this freezing mechanism, the magnetic field generation and its possible duration are not well understood.

An alternative scenario assumes a change in the heat transport mechanism of Mars as suggested by the model of early plate tectonics (Nimmo and Stevenson, 2000; Stevenson, 2001). During the phase of plate tectonics, the interior cools efficiently and not only a thermal dynamo but also a chemical dynamo is possible if the core cooled rapidly below its melting temperature. As soon as this regime is followed by stagnant lid convection, the mantle heats up and dynamo action stops until today (**Figure 15**). In the case of a thermal dynamo, the heat flow decreases below the critical value. In the case of a chemical dynamo, the end of the plate tectonic regime marks the time of the coldest interior. Thus, in the subsequent evolution, the core temperatures remain above the melting temperature and inner core growth and chemical dynamo action stop.

Impacts have been also identified to play a major role in the magnetic field generation. Some models predict that large impacts forming basins over 2500 km in diameter cease the dynamo action due to the heating of the mantle or the outermost core (Arkani-Hamed and Olson, 2010; Roberts et al., 2009). Such a thermal state suppresses core cooling that is unfavorable for core convection and could have led to the cessation of dynamo activity. Alternatively, it has been suggested that the thermal anomaly induced by a large impact and the formation of a hot molten iron layer from the impactor's core at the CMB can favor dynamo generation (Reese and Solomatov, 2010). Which scenario is most likely depends mainly on the dynamics in the core during merging of an iron diapir and a preexisting core – a process that is not well understood (Monteux et al., 2013).

The magnetic field data by MGS revealed that the Martian crust is strongly magnetized in the southern hemisphere while the northern hemisphere only shows weak signals (Langlais et al., 2004). Two possible reasons have been suggested for this dichotomy: A once more or less homogeneous magnetization may have been destroyed in the northern hemisphere by, for example, hydrothermal alteration (Solomon et al., 2005) or impacts (e.g., Mohit and Arkani-Hamed, 2004; Rochette et al., 2003). An alternative theory suggests that the dynamo itself produced a hemispheric field due to lateral heat flow variations at the CMB (Amit et al., 2011; Stanley et al., 2008). This hemispheric dynamo would produce strong magnetic fields in the southern hemisphere in case the heat flow out of the core below the southern hemisphere was stronger than below the northern hemisphere. A recent numerical model by Dietrich and Wicht (2013) shows, however, that these hemispheric dynamos reverse on timescales of about 10 ky – too fast to allow for a unidirectional magnetization of a thick crustal layer required to explain the strong magnetization in the southern hemisphere.

10.08.7 Io

10.08.7.1 Tidal Heating and Thermal Evolution

Io is unique in the solar system in that its primary source of internal heat is not radioactive decay but tidal dissipation (Peale et al., 1979). Io is the Galilean satellite nearest to Jupiter and it is the most volcanically active body in the solar system. Unlike most bodies in the solar system, which would require in situ methods to determine the heat flow, Io's surface heat flow can be estimated from remote observations of its thermal emission. From a global inventory of Io's thermal radiation from a variety of sources, McEwen et al. (2004) obtained a global heat flow estimate of $2.1 \pm 0.7\ \mathrm{W\,m^{-2}}$, while Veeder et al. (2004) gave $3 \pm 1\mathrm{W\,m^{-2}}$. The true value most likely falls in the range from 1.5 to 4 $\mathrm{W\,m^{-2}}$ (60–160 TW total). The heat production rate implied by the surface heat flow far exceeds that that can plausibly be produced by radioactive decay; thus, a different internal heat source must be active. Io's location so close to Jupiter causes it to be subject to intense tidal forces. The constantly varying tidal potential resulting from Io's eccentric orbit results in more than 10 m radial deformation of Io's solid surface every orbit (1.8 days). Viscoelastic dissipation of heat in the interior of Io due to the repeated tidal deformation is responsible for Io's large internal heat source. The tremendous heat flow measured at the surface of Io is the result of silicate volcanism, with typical inferred eruption temperatures of 1200–1400 K and extreme temperatures over 1800 K (McEwen et al., 1998). It is likely that the sulfur-based volcanism observed by Voyager is also driven by silicate magma.

Since the distribution of tidal heat within Io is strongly dependent on the variation of viscosity (Segatz et al., 1988), it has been proposed to use the distribution of volcanoes to infer the viscosity structure. The process of getting heat to the surface, however, is influenced by mantle convection, which will act to smooth out variations, and melt transport, which will be sensitive to lithospheric structures. Tackley et al. (2001) demonstrated that, even at high Rayleigh number, the spatial pattern of heating within the mantle should be reflected at the surface, and they favored an asthenospheric source for the heating. Hamilton et al. (2013) analyzed the distribution of volcanic centers based on clustering statistics and found that an asthenospheric model was preferred; however, a consistent 30–60° eastward offset of the observed pattern indicated that lithospheric structure, perhaps offset by nonsynchronous rotation, played an important role.

Despite the intensity of the volcanic activity on Io and the inferred high temperatures of its interior, Io supports some of the highest and steepest topography of any planetary body. Mountains up to 17 km high dot the surface (Jaeger et al., 2003; Schenk et al., 2001), and oddly, these are not volcanoes.

Instead, volcanic centers are generally depressions, while the mountains appear to be fault-bounded tectonic uplifts. The presence of such large topography seems incompatible with a lithosphere that must allow the transport of $\sim 2.5\ \mathrm{W\ m^{-2}}$ of heat.

A solution to this problem was found by O'Reilly and Davies (1981), who proposed a heat-pipe mechanism for heat transport through Io's lithosphere accomplished by melt transport through fissures. The most important implication of this model is that, as successive eruptions spread across the surface and cool, they bury the flows of previous eruptions, resulting in an advective transport of cold material from the surface downward. In order to match the observed heat flow, Io must be resurfaced globally by silicate magma to a depth of 1–2 cm every year. This is then the rate at which material is advected downward within the lithosphere. The equation for the temperature T in the lithosphere is then

$$\frac{k}{\rho c_\mathrm{p}}\frac{\mathrm{d}^2T}{\mathrm{d}z^2} = v\frac{\mathrm{d}T}{\mathrm{d}z} - \frac{H}{\rho c_\mathrm{p}} \qquad [23]$$

where k is the thermal conductivity, ρ is the density, c_p is the specific heat, z is the depth from the surface, v is the downward velocity (resurfacing rate), and H is the volumetric heat production. The temperature must match the surface temperature T_s at the surface and the melting temperature T_m at the base of the lithosphere. The solution in the case of no heat production is

$$T(z) = T_\mathrm{s}\frac{(T_\mathrm{m} - T_\mathrm{s})\left(\exp^{\lambda\xi} - 1\right)}{\exp^{\lambda} - 1} \qquad [24]$$

where $\xi = z/D$ is the depth normalized by the thickness of the lithosphere D and the dimensionless parameter $\lambda = Dv\rho c_\mathrm{p}/k$ is the advective velocity normalized by the conductive velocity scale. This can be related to the heat flux carried by melting F as follows:

$$\lambda = \frac{Dc_\mathrm{p}F}{k\left[L_\mathrm{f} + c_\mathrm{p}(T_\mathrm{m} - T_\mathrm{s})\right]} \qquad [25]$$

where L_f is the latent heat of fusion of the silicate rocks. For a heat flux of $2.5\ \mathrm{W\ m^{-2}}$ and a 30 km thick lithosphere, λ is about 10. Solutions for different values of λ are shown in Figure 16. For λ of 3, more than 80% of the thickness of the lithosphere is below 900 K, and for λ of 10, more than 95% of the lithosphere is cold enough to sustain elastic stresses for very long periods of time. This is how Io's lithosphere can support huge mountains while at the same time allowing a heat flux of $2.5\ \mathrm{W\ m^{-2}}$ to pass through.

What sort of melt fractions does the heat-pipe mechanism imply for the asthenosphere? It is straightforward to calculate the melt segregation velocity due to Darcy flow driven by the buoyancy of the melt (e.g., Scott and Stevenson, 1986):

$$\Phi v = \frac{k_\Phi g \Delta\rho}{\eta_\mathrm{m}} \qquad [26]$$

where Φ is the melt volume fraction (porosity), g is the gravitational acceleration, $\Delta\rho$ is the difference between the solid and melt densities ($\sim 500\ \mathrm{kg\ m^{-3}}$), η_m is the melt viscosity (~ 1000 Pa s), and k_Φ is the permeability, which is related to the porosity by a function of the form

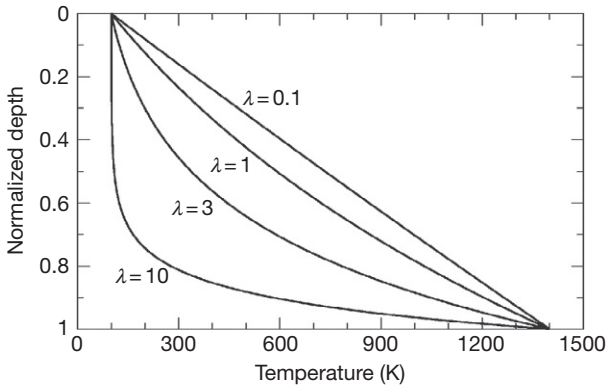

Figure 16 Temperature as a function of normalized depth for different values of λ; the normalized advective velocity defined in the text.

$$k_\Phi = \frac{b^2\Phi^n}{\tau} \qquad [27]$$

where b is a typical grain size (~ 1 cm) and n and τ are constants that are functions of the geometry of the melt. The dependence of k_Φ on grain size is overly simplified in this model, since real systems may have broad grain size distributions. Using the $1\ \mathrm{cm\ year^{-1}}$ resurfacing velocity (which is actually the melt flux Φv) and inserting experimentally determined values for the constants n (3) and τ (200) (Liang et al., 2001; Wark and Watson, 1998) result in an estimate for Φ between 10% and 20% (Moore, 2001). A global subsurface magma layer with a thickness of over 50 km and a rock melt fraction of 20% or more has been suggested by the magnetometer data of the Galileo spacecraft (Khurana et al., 2011). Melt fractions exceeding this will transport too much heat (the heat transported goes as k_Φ), thus cooling the asthenosphere and bringing the melt fraction back to the equilibrium value.

A rough estimate for the thickness of the asthenosphere may be obtained by extrapolating along the adiabat from the temperature at the top of the melt zone to the solidus:

$$d = \frac{\Delta T_\mathrm{m}}{(\mathrm{d}T/\mathrm{d}z)_\mathrm{m} - (\mathrm{d}T/\mathrm{d}z)_\mathrm{ad}} \qquad [28]$$

where $\Delta T_\mathrm{m} = \Phi L_\mathrm{f}/c_\mathrm{p}$ is the temperature excess required to reach a melt fraction Φ and the denominator is the difference between the slopes of the solidus ($\sim 0.8\ \mathrm{K\ km^{-1}}$) and the adiabat ($\sim 0.1\ \mathrm{K\ km^{-1}}$). Using the melt fractions estimated earlier in the text, the asthenosphere is 60–120 km thick. Below this is a mantle that is solid, but quite close to the solidus. Though we lack direct evidence, the core is most likely liquid, since even the pure iron solidus is below the silicate solidus. This simple analysis of melt segregation ignores the role of convection in heat transport within Io. Despite its broad applicability to planetary heat transport, however, heat transport in partially molten, convecting systems has not received thorough quantitative treatment. Unlike subsolidus convection, for which detailed parameterizations exist that incorporate many aspects of the physics of planetary materials (particularly the rheology of rocks), partially molten convection has been treated in an ad hoc fashion by tacking a melt segregation analysis such as that presented previously in the text onto a subsolidus convection parameterization.

This approach ignores the strong influence of melting and melt segregation on the convective flow itself, which is particularly important when the rheology of the convecting layer influences the heat production as it does in a tidally heated body such as Io.

10.08.7.2 Thermal and Orbital Evolution

The tidal heat source not only is capable of much greater heating rates but also evolves with the orbit of Io, since it depends on both the distance of Io from Jupiter (the semimajor axis) and the eccentricity of Io's orbit. Tidal heating is also very sensitive to the rheology of Io's interior. The heat source is therefore coupled to both the orbit and the interior temperature. This results in a very different thermal evolution for Io than for other bodies of similar size (e.g., the Moon).

The tidal heating of Io's interior is a result of the resonant orbital interactions between Io, Europa, and Ganymede, which have orbital periods that are in the ratio τ_I: τ_E: $\tau_G = 1:2:4$. The orbits of all three satellites have evolved together into what is called the Laplace resonance, where the conjunctions of each satellite with its nearest outward neighbor occur when the inner satellite is at perijove (nearest to Jupiter) and the outer satellite is at apojove (furthest from Jupiter), thus maximizing their separation. These repetitive alignments cause the orbits to remain elliptical, even though dissipation of tidal energy in the satellites should tend to circularize their orbits (while dissipation in Jupiter tends to make them more eccentric). In addition to the effects of dissipation on eccentricity, tides raised on the satellite tend to reduce the semimajor axis of the orbit, that is, the satellite tends to spiral inward. Thus, Io's orbital evolution is tightly coupled to the thermal evolution of its interior. Conversely, tides raised on Jupiter by the satellite cause the satellite to spiral outward (like the Moon). Thus, Io's actual rate of orbital migration represents a balance between dissipation in Io and dissipation in Jupiter. Indeed, this orbital migration is thought to be the process by which the resonant configuration is assembled (Yoder, 1979).

The coupled thermal–orbital evolution of Io (and Europa and Ganymede) is a complex dynamic system with a wide possible range of behaviors. The interior temperature is set by the balance between tidal heating and heat transport (convective or magmatic). Orbital evolution is driven by dissipation in Io. Fischer and Spohn (1990) studied the coupled system including a simplified orbital evolution (linearized about the Laplace resonance) and convective heat transport and recognized that there are multiple equilibriums for the thermal state of Io, as illustrated in **Figure 17**, a cartoon depicting the possible thermal equilibriums in a tidally heated body. Radioactivity (solid line) produces the same heating regardless of temperature, while tidal heat production (solid curve) depends strongly on temperature, increasing with temperature until the Maxwell time (viscosity over shear modulus) of the material approaches the tidal forcing period. At a critical temperature (T_c) slightly above the solidus, the shear modulus begins to decrease rapidly (Berckhemer et al., 1982), resulting in a drop in tidal heating. At the breakdown temperature T_b, the solid matrix loses coherence, and the material becomes dominated by the mechanical properties of the liquid and the tidal heating is greatly reduced. Convective heat transport (dashed curve)

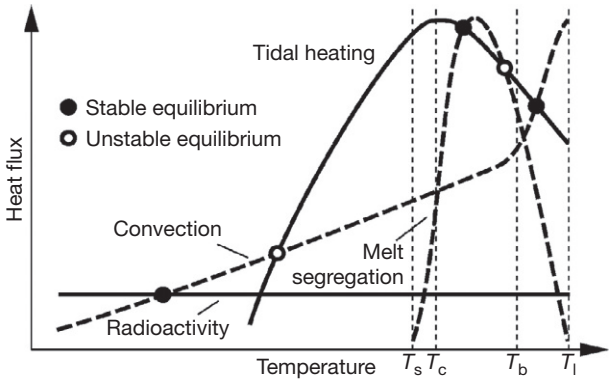

Figure 17 Cartoon depicting the possible thermal equilibriums (circles) in a tidally heated body. Heat sources (radioactivity and tidal heating) are shown as solid lines, and heat transport mechanisms (convection and melt segregation) are shown as dashed lines. Also marked schematically are the solidus T_s, critical T_c, breakdown T_b, and liquidus T_l temperatures.

increases with temperature, as the viscosity decreases, becoming extremely efficient as the liquidus temperature T_l is approached. Melt segregation (as described in the preceding text) can only occur between the solidus and liquidus and is not efficient above the breakdown temperature (since there is no longer any solid matrix for the melt to segregate from). Depending on the details of the heat production and transport processes, not all of these equilibriums may be realized, so we use a qualitative diagram to illustrate the possible range of behaviors. Fischer and Spohn (1990) identified the highest and lowest temperature equilibriums (the points where the solid tidal heat and radioactivity curves intersect the dashed convection curve) and noted that at times of low eccentricity, the high-temperature equilibrium may cease to exist. This is because low eccentricity shifts the tidal heat production curve downward, and it may fail to intersect the convective heat transport curve at all. Such episodes are followed by rapid cooling, as Io evolves toward the more common radioactivity-driven convective equilibrium. Moore (2003) investigated the tidal-convective equilibrium (for the current eccentricity, independent of the orbital evolution) and concluded that the high-temperature equilibrium, while present, cannot explain the observed heat flow; thus, a different heat transport process (melt segregation) was necessary.

Melt segregation can introduce additional equilibriums as shown in **Figure 17**. These equilibriums are necessarily between the solidus and liquidus temperatures (T_s and T_l). The simplified calculation given in **Section 10.08.7.1** required melt fractions of 10–20% to achieve equilibrium. This equilibrium is stable but may disappear at times of low eccentricity. Since this equilibrium is reached at temperatures lower than the convective equilibrium (this is a consequence of the high viscosity of rocks, even when partially molten), it is likely that Io never reaches the high-temperature convective equilibrium. Io's volcanic activity and high heat flow strongly suggest that Io is in (or near) an equilibrium state with melt segregation balancing tidal heat production. It is not known whether our roughly three decades of heat flow observations are representative of the long-term average, but if 10^{14} W is the rate of

energy dissipation in Io, then if we know the rate of dissipation in Jupiter, we can predict the rate at which Io's orbit is evolving. Unfortunately, the mechanisms by which tidal motions are dissipated in a deep atmosphere such as Jupiter's are not understood at present. We are therefore left with trying to measure the orbital evolution to estimate dissipation in Jupiter. A recent determination of the orbital accelerations of the Galilean satellites (Lainey et al., 2009) yields an orbital acceleration ($\dot{n}/n$) of $0.14 \pm 0.01 \times 10^{-10}$, a value consistent with the present heating rate. We can put certain bounds on the total outward migration of Io's orbit (assuming Europa and Ganymede have moved in concert) by assuming Io formed as close to Jupiter as possible (2.4 R_J) and evolved to its current orbital distance over the age of the solar system. This upper bound on the migration rate, however, is still much too low to account for Io's current dissipation rate, which depends on the maintenance of a high eccentricity (and thus high dissipation in Jupiter) (Yoder and Peale, 1981). We are therefore forced to conclude that Io's orbital evolution has not been steady over the age of the solar system or that the current heat flow does not represent a long-term average of the tidal dissipation. Either case is possible, since we do not know if the Laplace resonance is primordial or if it was assembled more recently by orbital migration. Furthermore, Io's surface heat flow represents dissipation integrated over some unknown transport time. However, if most of the heat is carried by melt segregation, as seems to be the case (in the preceding text and Moore (2003)), the transport time is short (tens of years), and the heat flow does reflect recent tidal dissipation (Lainey et al., 2009). A longer transport time regulated by convective motions would allow for the possibility of oscillatory states in which the heat flow and dissipation are out of phase (Fischer and Spohn, 1990; Hussmann and Spohn, 2004).

10.08.8 Summary

This chapter has reviewed the study of the interior structure, chemistry, and dynamics of terrestrial planetary bodies: Mercury, the Moon, Venus, Mars, and Io. There are many processes that connect these aspects of planetary interiors, many of which have been discussed here. Fundamentally, the dynamics of terrestrial bodies are driven by the transport of heat from the interior to the surface. Heat generation and transport are the processes that connect the structure and chemistry of a planetary body with its dynamic behavior, for example, volcanism, tectonism, and magnetism. The physical and chemical properties of planetary materials influence the mechanics of the planetary heat engine driving dynamics, while the dynamics in turn alter the physical and chemical properties of the planet's interior.

The density structure of each of the terrestrial bodies is roughly similar, with silicate mantles surrounding metallic cores, but the geometries vary significantly, from shallow mantles (Mercury) to very small cores (the Moon). The aspect ratio of the mantle can have a strong influence on the planform of convective motions in weakly convecting systems. The silicate mantles are similarly differentiated into crustal and mantle portions, with considerable variation in the thickness of the crust. The process of crustal formation, while universal, has not been identical on each of the terrestrial bodies. Both primordial (the Moon and Mercury) and evolved (Venus and Io) crusts exist today. This likely reflects the importance of crustal recycling and continuous crustal formation on the more active bodies. Crustal differentiation may have several different effects on the planetary heat engine. First, as a form of heat transport, melt segregation can be extremely efficient as seen at Io. For less active bodies, the crust can act both as an insulator for the mantle and as a sink for heat-producing elements. These effects have opposite influences on the temperature of the underlying mantle; the former tends to raise the temperature while the latter depresses it. Crustal material that is unevenly distributed may influence the temperature distribution in the upper mantle and the planform of convection, perhaps explaining the distribution of volcanism on Mars. Finally, melt segregation from the mantle may also be associated with devolatilization of the interior, which influences the rheology of the remaining mantle material.

The thermal evolution of the terrestrial planetary bodies through the history of the solar system has been studied by using parameterizations of heat transport through their mantles, but recently, modelers started to also use 2-D and 3-D convection models. Many physical processes have been incorporated in these models, including complex rheology (with temperature, pressure, stress, and composition dependence), partial melting, crustal formation, core heat flux, and inner core growth. These models are compared with observations of crustal and lithospheric properties, magnetic fields, tectonism, and volcanic activity. Significant uncertainties in the properties of the interiors of the terrestrial planets remain, so only general conclusions can be reached.

Mercury's magnetic field, if produced by dynamo action in the core, provides a very strong constraint on the heat transport through the mantle. If freezing of an inner core is required for dynamo action, this also places a constraint on the sulfur content of the core. Mercury's surface also records a few kilometers of radial contraction over its history in the form of lobate scarps. In order to generate a present-day magnetic field without completely freezing the core, convection in Mercury's mantle must be very weak or possibly have ceased altogether. A stiff rheology and a thin isolating crust seem to be required.

The situation on Venus is less well constrained, in part because much of the evidence of Venus' early history has been erased from the surface. Venus has been recently active (within the last 10^8 years and perhaps as recently as 10^5 years), but the cratering record is permissive of a wide variety of resurfacing scenarios. The strong correlation of gravity and topography at low harmonic degrees indicates that there are large-scale density anomalies in the mantle, likely the result of mantle convection. Whether Venus ever experienced a plate tectonic phase (or even several) is uncertain, but there is little present evidence for active plate tectonics. The observation that Venus lacks a magnetic field may be related to the relatively low heat transport efficiency of a single-plate planet with a rigid lid.

Unlike the more active bodies, which largely erase the influence of their initial conditions, the present state of the Moon may be strongly reflective of its formation. The thick lunar crust appears to be a primordial differentiate from a magma ocean that formed during the accretion of the Moon

from a hot debris disk orbiting the Earth after a giant impact. The differentiation of the magma ocean may have led to an initially unstable density stratification that drove an early episode of convection, but the segregation of heat-producing elements out of the mantle may result in only weak convective motions and fairly little internal cooling since then. The lunar core is small (< 500 km), and its composition is unknown. Certain lunar rocks have been magnetized, but whether this is evidence of an internally generated magnetic field is not certain. If there was an early lunar dynamo, it seems to have gradually decayed with time, beginning at about 4 Ga and ceasing at about 3 Ga. This perhaps reflects an early period of vigorous convection, but some mechanism is required to prevent dynamo onset earlier than 4 Ga unless the earliest remanent magnetizations are not measurable or existent although an early dynamo action was active.

Our knowledge of the interior and the evolution of Mars has been vastly improved by recent satellite and lander missions. The size of the Martian core is now better constrained, as is the average crustal thickness. Due to the ambiguity in these parameters as we do not know the composition and density of the core, mantle, and crust, only future seismic experiments may further improve our knowledge. Like the Moon, Mars has ancient, heavily cratered highlands, but unlike the Moon, the less cratered lowlands are not clearly impact basins. The ancient highlands, however, are regions of thickened crust, suggesting a primordial origin, though the mechanism and exact timing of the dichotomy formation are still debated. Geochemical evidence from SNC meteorites suggests that little mixing has gone on since early in Mars' history and thus that the bulk of the Martian crust was formed very soon after accretion. Furthermore, there are more and more data and models suggesting a wet interior – with a volatile content at least influencing the rheology if not even the petrology – that degassed with time due to crustal formation. Mars has been volcanically active into the recent past, and there are a wide range of tectonic features mostly related to volcanic construction. The discovery of strong magnetic anomalies associated with magnetized crust has led to new models of the early thermal history of Mars that include an episode of plate tectonics or an initially superheated core due to its formation to provide the required core cooling. Since that epoch, the activity of the Martian interior has been gradually declining. The crustal dichotomy provides a spatially variable boundary condition to the convecting mantle and may provide a means for keeping some partial melt and for focusing it at Tharsis.

Although it is an outer planet satellite, Io is essentially a terrestrial body, with a silicate mantle and a metallic core. Io is unique, however, in that its internal heat source is tidal dissipation rather than radioactive decay. This ties the heat production in the interior to the internal physical state through the rheology. Io is also unique in that the dependence of tidal heating on the material properties is such that the internal temperature is kept above the solidus. This leads to massive amounts of volcanic activity and makes Io the only terrestrial body to transport heat primarily by melt segregation. Io today may provide us an opportunity to study processes that were in effect on the other terrestrial bodies only briefly in their earliest histories. The constant resurfacing by volcanic eruption has erased all evidence of impacts on Io's surface and produces strong compressional stresses as the surface subsides beneath subsequent flows. These stresses lead to large fault-bounded massifs, some of the tallest in the solar system. Ionian volcanoes, however, are broad, low-relief structures, perhaps because the abundant sulfur deposits on the surface and in the crust are easily weakened by the locally high heat flow.

The study of terrestrial planet interiors has advanced significantly in the last decades, driven by improvements in modeling, increasing computing power, and new observations of Mercury, Venus, Mars, the Moon, and Io. The coming decades will see additional missions to Mercury, the Moon, Mars, and the outer solar system that will expand our knowledge of terrestrial bodies. Extrasolar terrestrial planets allow us to put the formation of our own planetary system in a broader context. Until today, four exoplanets, that is, CoRoT-7b (Bruntt et al., 2010; Hatzes et al., 2011; Léger et al., 2009), Kepler-10b (Batalha et al., 2011), Kepler-36b (Carter et al., 2012), and Kepler-78b (Howard et al., 2013; Pepe et al., 2013), have been detected, from which we know mass and radius and that can be characterized as terrestrial. Our understanding of the properties and behavior of planetary materials, especially at high temperature and pressure, will continue to grow through experimentation and observation. Looking further ahead, there will come a day when terrestrial planetary bodies will be directly explored by human beings, and a new era of terrestrial planet geology will dawn. Though that day may be far in the future, that achievement will build upon the research summarized in this chapter, extending and refining our understanding of the terrestrial planets.

Acknowledgments

We thank Stephen Hauck and Gregor Golabek for their helpful reviews that improved the manuscript.

10.09.1 Introduction

The Earth is but one of the many planetary bodies in the solar system (in this chapter, a 'planetary body' encompasses any solid body orbiting the Sun that is larger than a few hundred kilometers in diameter) and therefore represents only one datum. It is essential to examine geologic processes on other planetary bodies to gain the most complete understanding. If a model works well on Earth, a vital test for the validity of that model is to determine if it works equally well when applied to places in the solar system with different ambient conditions (e.g., gravity, surface pressure, and atmospheric composition). Thus, the investigation of volcanic and tectonic processes on other planetary bodies provides insight into those same processes operating on Earth.

In the last 20 years, terabytes of data have poured down to Earth from spacecraft orbiting Venus, Mars, the Moon, Saturn, Jupiter, and even a few asteroids. Information gleaned from these missions has revealed extraterrestrial processes that in some cases are quite familiar and, in others, remain poorly understood. In this chapter, the current understanding of volcanic and tectonic processes operating in the inner solar system (Mercury, Venus, the Earth/Moon, and Mars) are summarized. A single chapter cannot possibly cover all the information available – the entire outer solar system is avoided here – and therefore, the reader is encouraged to pursue additional readings (see, e.g., Watters and Schultz, 2010).

10.09.2 Planetary Volcanism and Tectonics

10.09.2.1 Tectonics

Both volcanic and tectonic processes are controlled largely by lithospheric and asthenospheric behaviors on Earth; other planetary bodies large enough to experience differentiation (larger than a few hundred kilometers in radius) should also have (or have had in the past) similar mechanical layering. Earth's tectonics are dominated by the lateral movement of rigid lithospheric plates over the weaker asthenosphere. This style of tectonism – plate tectonics – is unique to Earth and localizes tectonic activity primarily to plate boundaries. The other terrestrial planets (see Table 1) display movement and deformation of a single, continuous lithospheric shell. On the Moon, tectonics are locally controlled by large ($>10^2$ km radius) impact basins. Mars' tectonics are regionally controlled by both large impact basins and volcanic provinces (such as the Tharsis region). Large impact basins have tectonic signatures on Mercury, but there are also more global patterns of tectonism that are unique among the terrestrial planets. Venusian tectonism is expressed almost globally across the Venusian plains. Locally, quasicircular tectonic terrains called 'coronae' (up to thousands of kilometers across) and rift valleys called 'chasmata' reveal lithospheric extension and compression.

The icy satellites of Jupiter and Saturn also clearly display tectonic features, but there are fewer data available to constrain the mechanical layering inside those planetary bodies. Observations to date support that most of these icy satellites are also 'one-plate planets' whose tectonics are controlled mostly by large impact basins and tidal forces, with volcanic processes exhibiting local dominance.

10.09.2.2 Planetary Lithospheres

Tectonics are the movements of the lithosphere, so to understand planetary tectonics, it is first necessary to learn about the properties of these extraterrestrial lithospheres and the limitations of that knowledge (see Chapter 10.05, and references

Table 1 Physical parameters of the terrestrial planets

Planet	*Equatorial radius (km)*	*Bulk density (kg m^{-3})*	*Surface gravity (m s^{-2})*	*T$_E$*[a]	*Atmospheric pressure*[b] *(Pa)*
Mercury	2439	5430	2.78	172	0
Venus	6051	5250	8.60	22	9.12×10^6
Earth	6378	5520	9.78	34	1.01×10^6
Moon	1738	3340	1.62	103	0
Mars	3393	3950	3.72	126	600

[a]From Melosh (2011), Table 4.1.
[b]Value given for sea level (Earth) or mean planetary radius.

therein). Earth's internal layering, and the geophysical properties of those layers, has been revealed through painstaking collection and analyses of seismic data. As every geology initiate knows, a minimum of three seismic stations are required to locate the epicenter of an earthquake. Neither Mercury nor Venus has supported seismometers. Although both Viking Landers 1 and 2 contained seismometers, only Viking Lander 2 returned seismic data from Mars. Apollo missions 12, 14, 15, and 16 successfully deployed seismometers on the lunar surface (the Apollo Passive Seismic Experiment, or PSE) that continued to radio data to Earth until they were switched off in 1977 (cf. Nakamura, 1980, 2003, 2005). All of these seismometers were necessarily deployed on the lunar nearside, providing suboptimal data collection. Recent reprocessing of the PSE data, however, reveals the vital information about the structure and composition of the lunar interior (Weber et al., 2011; **Chapter 10.03**): the Moon likely contains a solid inner core, a liquid outer core, and a partially molten boundary layer (similar to Earth's internal structure). These new insights using old data are granted by improved technologies and suggest that we can look forward to improved understanding of deep planetary interiors.

Information about extraterrestrial lithospheres, and their elastic thicknesses (T_E), has come primarily from topography and gravity models (Belleguic et al., 2005; Grott and Breuer, 2009; Kiefer and Li, 2009; McGovern et al., 2002; Wieczorek, 2007; Wieczorek et al., 2006, 2013; **Chapter 10.05**). The lithosphere is defined as the outermost mechanical (as opposed to chemical) layer of a planetary body that behaves rigidly over geologic timescales. The effective lithospheric elastic thickness characterizes the apparent strength of the lithosphere. On Earth, the value of T_E and the depth to the base of the mechanical lithosphere are approximately the same for oceanic lithosphere, but can differ widely for continental lithosphere (e.g., Burov and Diament, 1995). Most simply, T_E is controlled by lithospheric composition, surface temperature, and heat flow (Melosh, 2011):

$$T_E = \frac{k\left(\frac{T_m}{2} - T_s\right)}{q_s} \quad [1]$$

where k is the thermal conductivity (J s^{-1} K^{-1}), T_s is the surface temperature of the planet, T_m is the melting temperature of the lithosphere, and q_s is the heat flow from the planet's surface (J s^{-1} m^{-2}). Thermal conductivity does not have a wide range among geologic materials (e.g., Navrotsky, 1995). Using this equation, and reasonable geologic assumptions, gives T_E of ~34 km for Earth; ~100 km for the Moon and Mars; ~20 km for Venus; and almost 200 km for Mercury (Melosh, 2011). These numbers predict distinct responses to volcanic loading or upwelling on each planet, for example.

It is important to note, however, that the values for T_E calculated by eqn [1] can give quite different values from those calculated using other methods. For example, Zuber et al. (2010) estimated T_E for Mercury to be on the order of 30–60 km, based on topographic measurements of contractional features. Smith et al. (2012) used orbital data collected from the MESSENGER (MErcury Surface, Space ENvironment, GEochemistry, and Ranging) spacecraft to estimate Mercury's T_E to be only 70–90 km. These variations reflect a combination of data resolution and the complexities (such as lithospheres composed of layered materials with different rheologies) inherent in the parameters controlling T_E.

Lithospheric or crustal deformation is responsible for the tectonic features observed on other planetary bodies. The crust, a portion of the lithosphere, is distinguished from the lithosphere by composition: in differentiated bodies, the crust is the outermost layer, distinguished by having the lowest density. On Earth, the crust is the outermost portion of the lithosphere, and it is likely that similar arrangements exist on other terrestrial planets. The large density contrast between the crust and mantle makes it somewhat simpler to model the crustal thickness than the lithospheric thickness.

Modeling the thickness of the crust and lithosphere requires detailed measurements of the surface topography and gravity. These data sets currently exist for Mars and Venus; MESSENGER data from Mercury and GRAIL (Gravity Recovery and Interior Laboratory) data for the Moon (see **Table 2**) are improving our modeling capabilities for those planetary bodies. Mars' crust displays a strong dichotomy: in the southern highlands, the crust is ~60 km thick – about twice as thick as in the northern lowlands (Neumann et al., 2004). On Venus, the spatial resolution of the gravity and topographic data provide fewer model constraints; recent work (James et al., 2013) suggests that the mean crustal thickness on Venus is 8–25 km. Data from GRAIL indicate a lunar crustal thickness between 34 and 43 km (Wieczorek et al., 2013). Acknowledging that the available data are relatively poor quality for the southern hemisphere of Mercury, Smith et al. (2012) calculated crustal thicknesses ranging from ~20 to 80 km, with a mean of 50 km.

10.09.2.3 Mare-Type Wrinkle Ridges

Mare-type wrinkle ridges (or, simply, 'wrinkle ridges') appear on every terrestrial planet (Watters, 1988), but are relatively rare on Earth (**Figure 1**). These features were first described on the lunar surface, where they are linear to arcuate in planform and have a superficial resemblance to folds (or wrinkles) in a rug – hence their name. Complete wrinkle ridges consist of a broad topographic arch topped by a narrow sinuous ridge (Golombek et al., 2001; Watters, 1988); locally, the sinuous ridge may meander off of the broad arch. They are asymmetrical in a topographic profile drawn perpendicular to their long axis, and the sense of asymmetry may change along ridge length. Wrinkle ridges are now recognized to be blind (not intersecting the surface) thrust faults (Golombek et al., 2001;

Table 2 Missions measuring the highest-resolution topography of the terrestrial planets

Planet	*Mission*	*Instrument*	*Year*	*Topographic resolution (m): footprint size*	*Relative vertical accuracy (m)*
Mercury	MESSENGER	Mercury Laser Altimeter (MLA)	2008 to present	15–100 m	0.10

Schultz, 2000) through layered materials, with surface folding, although the precise nature of the faulting remains unclear (Golombek et al., 2001; Schultz, 2000; Watters, 2004; Zuber, 1995). The size and spacing of parallel wrinkle ridges can be used to determine the total thickness of the deformed material (e.g., Watters, 1993; Zuber, 1995): large spacing (10–10^2 km) reflects a greater thickness of deformed material than does small spacing (10s of kilometers) (Montesi and Zuber, 2003a,b; Watters, 2004; Zuber and Aist, 1990).

10.09.3 The Moon

10.09.3.1 Lunar Tectonism

Lunar tectonics are dominated by large (>10^2 km across) impact basins (Watters and Johnson, 2010; Wilhelms, 1987). Wrinkle ridges and linear or arcuate troughs are commonly found within or adjacent to impact basins (Watters and Johnson, 2010). Wrinkle ridges and lobate scarps are compressional features; linear or arcuate troughs are generally interpreted to be graben and therefore extensional. Lobate scarps are more broadly distributed across the lunar surface (Watters and Johnson, 2010) and are interpreted to be thrust faults (Binder, 1982; Watters et al., 2010).

Lunar impact basins on the nearside are filled with various amounts of basalts; these lowlands are referred to as maria (mare = singular). Wrinkle ridges are found within the maria and are typically both radial and concentric to the basin center (Maxwell et al., 1975; Watters and Johnson, 2010). Wilhelms (1987) pointed to wrinkle ridge rings within large lunar basins as marking the location of buried basin ring complexes, suggesting that premare topography may play an important role in the spatial distribution of lunar wrinkle ridges. Alternatively, lithospheric loading by basaltic lava may have caused basin subsidence, resulting in concentric and radial compressional stresses (Freed et al., 2001; Maxwell et al., 1975; Solomon and Head, 1979).

Linear or arcuate troughs (graben) are also associated with large lunar impact basins and their maria. They are interpreted to be graben because of their flat floors, inwardly dipping walls, and symmetrical topographic cross sections (**Figure 1**); debate remains about the precise nature of these graben: they may be the expression of near-surface dikes (Head and Wilson, 1993) or have been formed by localized basin stresses (Golombek, 1979). These graben are typically located entirely within maria deposits (and therefore are likely caused by basin-controlled extension) but locally may extend for a few kilometers into the adjacent highlands. No graben are observed on the lunar farside (Watters and Johnson, 2010) until recently: the Lunar Reconnaissance Orbiter Camera (LROC) revealed small-scale (locally as shallow as ~1 m) graben in the farside highlands and mare basalts (Watters et al., 2012a). These graben may be as young as 50 My (Watters et al., 2012a).

A unique class of impact crater, floor-fractured craters display a complex, spider-web-like network of graben on their otherwise flat floors (**Figure 2**; Wichman and Schultz, 1995; Wilhelms, 1987). Alphonsus crater (2.1° E, 13.5° S) is a type example. The current consensus is that these types of graben networks are formed by localized uplift of the crater floor, although the specific cause of the uplift remains unclear. Results of numerical modeling (Dombard and Gillis, 2001) suggest that viscous relaxation of the crater floor is unlikely to cause floor fractures in craters with diameters < 60 km. Uplift caused by a local igneous intrusion is the most likely

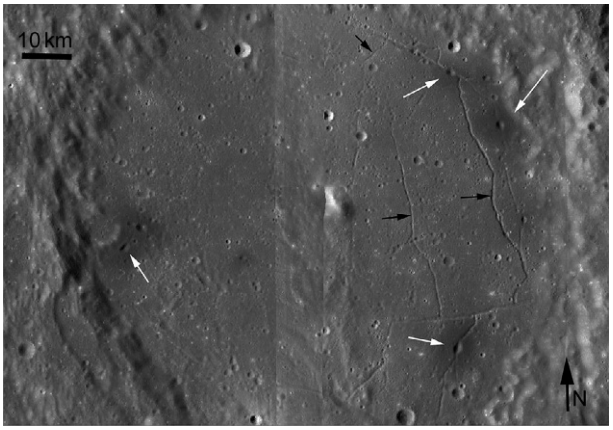

Figure 2 Alphonsus crater (2.1° E, 13.5° S) on the Moon. Black arrows point to troughs (graben) on the crater floor; white arrows point to dark mantling deposits (pyroclastic deposits). Image from Lunar Reconnaissance Orbiter Wide-Angle Camera, courtesy of NASA/JSC/ASU.

explanation for floor fracturing of larger impact craters (Wichman and Schultz, 1995).

The spatial correlation of wrinkle ridges and linear or arcuate graben with lunar maria strongly suggests a causal (and therefore temporal) relationship. Certainly, many of the largest lunar impact basins on the nearside are associated with mass concentrations ('mascons') that could also be related to deformation of basin-weakened lithosphere (Solomon and Head, 1979, 1980). Crosscutting relations and impact crater size–frequency distributions suggest that both wrinkle ridges and graben formed shortly after the maria were deposited. The detailed examination of maria deposits cut by lunar graben, combined with impact crater size–frequency distributions, suggests that no maria younger than 3.6 Ga (±0.2 Ga) are crosscut by linear or arcuate graben (Lucchitta and Watkins, 1978). In contrast, wrinkle ridges are observed to deform the oldest (~4.0 Ga) and the youngest (1.2 Ga) maria (Hiesinger et al., 2003).

Lobate scarps (interpreted to be thrust faults (Schultz, 1976)) have been estimated to be even younger than the youngest wrinkle ridges, based on their relatively fresh appearance (**Figure 3**) and impact crater size–frequency distributions (Binder and Gunga, 1985). It has been proposed that some lunar lobate scarps may even currently be active (Watters et al., 2010, 2012a).

10.09.3.2 Lunar Volcanism

Lunar volcanism is concentrated on the lunar nearside within impact basins. These maria cover $\sim 6.3 \times 10^6$ km^2 (Head, 1976) with a volume of $\sim 5.0 \times 10^6$ km^3 (Budney and Lucey, 1998; Hiesinger et al., 2002; Horz, 1978). The Apollo astronauts returned over 350 kg of lunar material (NASA, 2007), and it is primarily from these samples (as well as rare meteorites from the Moon that have struck the Earth) that we know the composition of lunar lavas. By using these lunar samples as 'ground truth' for comparison with satellite data, the composition of the lunar surface is fairly well constrained.

[c]Kargel et al. (1993).
[d]Best and Christiansen (2001).

The lunar maria are 'basalts,' but these are unlike any basalts observed on Earth, and there is a range in lunar basalt compositions (see **Table 3**; Shearer et al., 2006). Although both lunar and terrestrial basalts share a relatively low SiO_2 content (<54 wt%), the abundances of the remaining oxides belie this similarity. Lunar basalts have more iron and less aluminum than typical terrestrial basalts, giving them a high melting temperature (~1400 °C) and a low viscosity (<1 Pa s at liquidus temperature) (Murase and McBirney, 1970). Furthermore, H_2O and CO_2 are the most abundant volcanic volatiles on Earth (e.g., Schmincke, 2004); in the anhydrous and reducing environment of the Moon, CO is the most probable volatile (Wilson and Head, 1981). In addition to these

compositional differences, the lunar volcanic environment has a lower gravity, no atmosphere, and a surface temperature that ranges from 126 to 373 K (see Wilson and Head, 1981). It should not be surprising, therefore, that lunar volcanism displays different morphologies than we see for basaltic volcanism on Earth.

Lunar basalts are concentrated in large impact basins on the nearside, although they also exist as lava 'ponds' (<2000 km^2) (Yingst and Head, 1997). Maria that are obscured by superposed, higher albedo material (such as impact crater ejecta) are termed 'cryptomaria' (Antonenko et al., 1994). The stratigraphic position of cryptomaria suggests that it represents some of the oldest volcanism on the Moon. However, this same stratigraphic position makes it difficult to identify and study.

The low viscosity of lunar basalts makes the preservation of lava flow margins rare, although some fantastically large (>1200 km long) examples can be seen in the Imbrium basin (Schaber, 1973; Schaber et al., 1976). Furthermore, low-viscosity lavas are unlikely to pile up around the vent to create tall volcanic constructs. Finally, low-viscosity lavas are likely to flood low-lying terrain, potentially burying their own vents. Thus, although lunar lavas comprise 17% of the lunar nearside, vents and edifices are relatively rare and tend to be concentrated in a few geographic locations: the Marius Hills region, the Aristarchus plateau region, and the Gruithuisen domes.

The Marius Hills region (**Figure 4**) is characterized by mounds and hills that have been interpreted to be volcanic domes and cones (Weitz and Head, 1999). Domes have flank slopes of 2° and cones are steeper; both have basal diameters <25 km. All currently available data are consistent with these hills being basalt (rather than a more evolved, silica-rich, viscous lava). The analysis of recently acquired topographic data from the Lunar Orbiter Laser Altimeter led Spudis (2011) to suggest that the entire Marius Hills complex is a large (330 km across and 3.2 km tall) shield volcano peppered with smaller parasitic vents. Lawrence et al. (2013) stated that the Marius Hills represent eruptions of mare materials and the morphological variability was caused by a range of eruption and emplacement conditions.

Surrounding the Marius Hills is a high spatial density of sinuous rilles (**Figure 4**). Sinuous rilles are long (up to hundreds of kilometers) sinuous troughs that maintain a relatively constant width (generally <5 km) along their length. These troughs are generally u-shaped in cross section (as opposed to v-shaped) and some of them originate in circular or irregular depressions (Greeley, 1971; Schubert et al., 1970). These rilles formed via lava, although there remains debate as to whether they are erosional (lava downcutting into the preexisting surface by melting and assimilating the country rock) or constructional (e.g., lava tubes whose roofs have collapsed over time or drained lava channels) features (e.g., Williams et al., 2000 and references therein). There are hundreds of sinuous rilles on the lunar surface, and it is unlikely that all of them formed in precisely the same way: it is probable that some combination of constructional and erosional processes is responsible for their formation (Roberts, 2013).

The low viscosity of lunar basalts and lack of water would predict an abundance of effusive volcanism (i.e., lava flows) rather than explosive volcanism. However, astronaut Jack Schmidt returned a sample of orange soil from Apollo 17; analyses revealed that the soil contained microscopic droplets of orange volcanic glass. Subsequently, green glass droplets were identified in the Apollo 15 samples. These droplets formed by explosive eruptions of lunar basalts (Meyer, 2005): in the absence of atmospheric drag, the magma fragmented by bubbles (probably of CO) popping on the lunar surface formed microscopic beads. Dark mantle deposits (DMDs) are easily observed on the floor of Alphonsus crater (**Figure 3**), and the spatial association of these DMDs with small craters and the floor fractures (interpreted to be graben) indicates that the DMDs are pyroclastic deposits (Weitz et al., 1998). DMDs are now recognized across the lunar maria (Weitz et al., 1998), representing explosive lunar eruptions.

The timing of lunar volcanism is determined through a combination of (1) radiometric dating of Apollo-returned samples, (2) careful geologic mapping to determine maria stratigraphy, and (3) impact crater size–frequency distributions. Radiometric dating of Apollo-returned samples gives ages of 3.6–3.9 Ga (Apollo 11 and Apollo 17 high-titanium basalts) to 3.16–3.4 Ga (Apollo 12 and 15 low-titanium basalts) (Nyquist and Shih, 1992; Snyder et al., 2000). Mapping and impact crater size–frequency distributions suggest that the youngest maria patches on the lunar nearside may be only 1.0–1.2 Ga (Hiesinger et al., 2003; Schultz and Spudis, 1983). Lava production on the Moon appears to have peaked 3.5–3.8 Ga (Shearer et al., 2006), indicating that the Moon is a volcanically 'old' planet. However, there is evidence that Ina, a D-shaped crater about a kilometer across (18.6° N, 5.3° E), may still be actively degassing (Schultz et al., 2006) although the amount and type of volatiles remain unknown.

10.09.4 Mars

10.09.4.1 Martian Tectonics

Mars, like the Moon, is a one-plate planet (**Figure 5**), but can be divided into three distinct physiographic, topographic, and geologic provinces: (1) the northern lowlands, (2) the southern highlands, and (3) the Tharsis region (see Golombek and

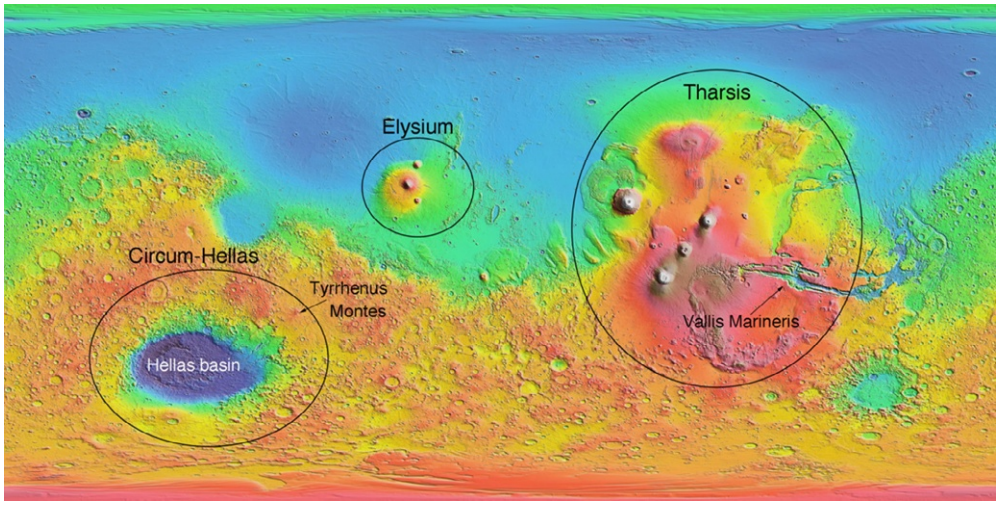

Figure 5 Topographic map of Mars: blues and purples are low elevations; reds and whites are high elevations. The whites in the Tharsis region are ~25 km above mean planetary radius; the purples in Hellas basin are about 12 km below mean planetary radius. Image courtesy of JPL/NASA.

Phillips, 2010 and references therein). The northern hemisphere is topographically low and relatively smooth, whereas the southern hemisphere is rugged with impact craters and is topographically higher (McCauley et al., 1972); this is commonly referred to as the 'crustal dichotomy.' Locally, the dichotomy boundary is marked by a scarp that may be as tall as 5.5 km (Aharonson et al., 2001; Watters et al., 2007); elsewhere, volcanics and erosional processes have modified (or buried) the nature of the boundary. There is evidence for some movement along this scarp in the form of compressional (lobate) scarps, extensional features such as graben, and broad topographic signatures of lithospheric flexure (Watters, 2003a,b; Watters et al., 2007). The similar ages for terrains north and south of the dichotomy boundary (e.g., Frey, 2006; Watters et al., 2007) argue against a plate-tectonic genesis for the dichotomy boundary. The origin of this dichotomy remains a mystery (e.g., Citron and Zhong, 2012), but it appeared early (>3.6 Ga) in Mars' history (Frey, 2006; Frey et al., 2002; Hartmann, 2005; Hartmann and Neukum, 2001; Nimmo et al., 2008; Watters et al., 2007).

Although ancient seafloor spreading has been proposed as a possible origin for the crustal dichotomy (Sleep, 1994), there is no morphological or chronological evidence for plate tectonics at the dichotomy boundary (e.g., Frey, 2006; Pruis and Tanaka, 1995). However, there is an interesting magnetic signature in the oldest portions of the southern highlands (Acuna et al., 2001). The alternating bands of strong/weak magnetic fields in the southern highlands are reminiscent of the alternating magnetic bands found in the ocean crust around Earth's mid-ocean ridges and require that Mars once generated its own active global magnetic field. The location of the magnetic pattern requires that Mars' dynamo stopped working within a few hundred million years of planetary formation (Acuna et al., 2001; Hartmann and Neukum, 2001), leaving behind no geologic signature of rifting associated with the magnetic stripes.

The Tharsis region is the largest volcanic province on Mars, and its tectonic influence spans over half of the planet. Volcanic products (primarily lava flows) constructed a pile ~5000 km across and 9 km tall during the first billion or so years of Mars' history (Carr and Head, 2010; Phillips et al., 2001); currently, the volcanic pile is approximately 10 km high. The enormous mass of this volcanic pile deformed the martian lithosphere, creating a circumferential trough, an antipodal high, and gravity anomalies (Phillips et al., 2001). Circumferential wrinkle ridges surrounding the Tharsis region (indicating compression) are particularly visible in Lunae Planum (Watters, 1988, 1993; Zuber and Aist, 1990), where their regular spacing (~60 km; Zuber, 1995) suggests that the thickness of the deformed layer is also ~60 km (a 'thick-skinned' interpretation). Alternatively, the wrinkle ridges may be the result of deformation of only the volcanic plains (a few kilometers thick – a 'thin-skinned' interpretation) (Watters, 2004). Most striking is the largest canyon in the solar system, Vallis Marineris (4000 km long, up to 7 km deep, and 200 km wide) (**Figure 5**). The parallel, inward-dipping walls and flat floor of this canyon are consistent with Vallis Marineris being a large rift valley system. Geophysical modeling results show that the distribution and orientation of most tectonic features around the Tharsis region can be explained by flexural loading of the lithosphere, using present-day values for gravity and topography (Golombek and Phillips, 2010). These results, combined with the timing of the deformation, indicate that the martian lithosphere beneath the Tharsis region has remained unchanged since about 3.6 Ga. Recent modeling by Beuthe et al. (2012) suggests that the elastic lithosphere thickness varies throughout the Tharsis region, being thickest beneath Olympus Mons and thinner elsewhere.

However, the thickness of Mars' elastic lithosphere is not everywhere the same nor was it likely the same at every stage in Mars' history. Published elastic lithosphere thickness estimates range from a mere 2 km thick beneath portions of Ascraeus Mons in the most recent period of Mars' history to possibly more than 300 km thick beneath Apollinaris Mons during the same time (see Golombek and Phillips, 2010, and references therein).

Mars displays a staggering variety of tectonic features: wrinkle ridges (thrust faults) and linear to arcuate troughs (graben) are abundant, but strike-slip faults are rare (Andrews-Hanna et al.,

2008; Schultz, 1989; Watters, 1992). Those documented to date are primarily accommodation features, marking regions where the regional stress field experiences a change in orientation (Andrews-Hanna et al., 2008). Andrews-Hanna et al. (2008) mapped two populations of strike-slip fault west of the Tharsis region, with individual offsets as long as 9 km. Stratigraphic relations suggest that these faults were active over a roughly 2 Ga period (from >3.8 to <2.8 Ga). Strike-slip faults located northwest of the Tharsis region are younger, active within the last ~2.0 Ga of Mars' history. The shift in space and time of strike-slip faulting around the Tharsis region requires a changing stress field around the Tharsis region with time.

Martian tectonic features are concentrated around volcanic provinces and large impact basins. As technology and image resolution improve, smaller and smaller tectonic features can be observed, but the same general patterns are still evident.

Martian wrinkle ridges are morphologically similar to their lunar counterparts (**Figure 6**) (Schultz and Watters, 2001; Watters, 1993, 2003a). They are most commonly found deforming plains materials that were emplaced around 3.2–3.6 Ga (Hartmann and Neukum, 2001; Hartmann, 2005). Near the Tharsis region (e.g., in Lunae Planum), wrinkle ridges are circumferential to the approximate center of the Tharsis region and their topography steps downward away from the Tharsis region, consistent with a thrust fault origin (Watters, 1993). Away from the Tharsis region, in Hesperia Planum, wrinkle ridges form roughly orthogonal, crosscutting networks that are oriented radial and circumferential to Hellas basin. Goudy et al. (2005) determined that the radially oriented ridges are younger than the circumferential ridges, indicating a change in the regional stress field over time. Hesperia Planum also reveals ridge rings (**Figure 6**) that are interpreted to form over buried impact craters (e.g., Watters, 1993). Hesperia Planum deposits are <3 km thick (Ivanov et al., 2005) so it is unlikely these wrinkle ridges deform the entire lithosphere.

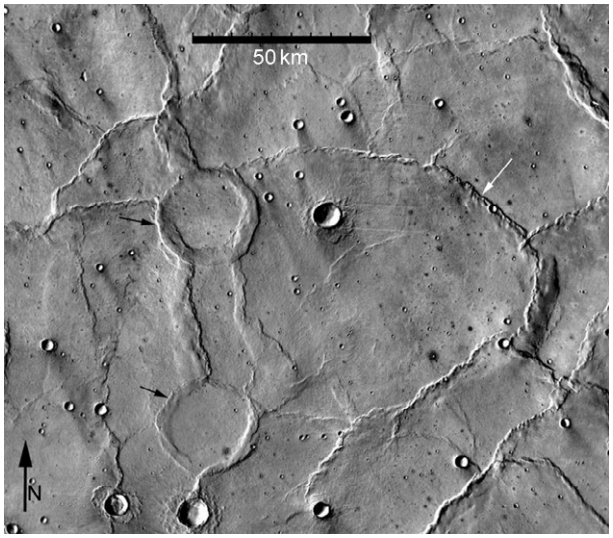

Figure 6 Small, circular ridge rings (black arrows) and a large, ellipsoid ridge ring (white arrow) in Hesperia Planum, Mars. Note intersecting wrinkle ridges throughout the image. Image centered at 115.3° E, 19.0° S. THEMIS daytime IR mosaic rendered using JMars. Image courtesy of NASA/JPL/ASU.

Similar to the Moon, Mars also displays lobate scarps that are interpreted to be lithospheric scale thrust faults (Schultz and Tanaka, 1994). They are larger than wrinkle ridges (both longer and taller), and shortening is estimated to be one to two orders of magnitude greater along lobate scarps than along wrinkle ridges (Watters, 1993).

Graben on Mars range from a few meters across to kilometers across. The interpretation of high-resolution (<3 m per pixel) images shows evidence for erosion and deposition within narrow graben, suggesting that the primary morphology could be obscured (Golombek and Phillips, 2010). The subsurface character of these narrow graben remains unclear. Bounding faults that dip inward at ~60° would intersect at some depth beneath the surface that may represent a mechanical discontinuity. Alternatively, one fault could terminate against a deeper master fault (Schultz et al., 2007). It has been proposed that most martian graben are the expression of near-surface dikes (e.g., Ernst et al., 2001; Mege and Masson, 1996; Scott and Wilson, 2002; Wilson and Head, 2002). In contrast, pit crater chains on Mars – which appear to be genetically related to some narrow graben (Wyrick et al., 2004) – are formed primarily by dilational normal faulting.

10.09.4.2 Mars' Volcanism

To date, all available data indicate that volcanism on Mars is mafic and probably basaltic. Evidence from remote sensing data, volcanic morphology, Mars' meteorites, and in situ analyses of Martian rocks all support basaltic volcanism (**Table 3**). Remote sensing detection of possible evolved (silica-rich) lavas in Nili Patera is best explained by being hydrothermal deposits rather than lavas or igneous intrusions (Skok et al., 2010). Mars has a thin (<600 Pa at mean planetary radius, or mpr) atmosphere (roughly 0.6% of Earth's) that is 95% CO_2 (NASA, 2010). Although liquid water is not currently stable on the surface of Mars, there is abundant morphological (e.g., Carr, 1996) and geochemical (e.g., Morris et al., 2010) evidence that liquid water existed on the surface in the past. Water ice is found on Mars today, being most abundant in the polar regions (Bibring et al., 2004; Clark and McCord, 1982) and in the subsurface (Schorghofer and Forget, 2012). Thus, when investigating volcanism on Mars, it is important to look for the evidence of interaction between magma (lava) and water (ice).

There are three main volcanic provinces on Mars: (1) the Tharsis region, which boasts both the tallest (Olympus Mons) and widest (Alba Mons) volcanoes in the solar system; (2) the Elysium region; and (3) the circum-Hellas region, which contains some of the oldest volcanoes on Mars. In addition, Mars appears abundantly covered in 'ridged plains,' which are interpreted to be thinly layered basalt flows (Greeley and Guest, 1987; Scott and Tanaka, 1986) that were largely emplaced around the same time (~3.2 Ga). Effusive eruptions appear to have been more common than explosive eruptions, although it is possible that the explosive eruptions have not been fully identified yet (e.g., Kerber et al., 2011).

Both the Tharsis and Elysium regions are dominated by shield volcanoes. The Tharsis region contains four large shield volcanoes: Olympus, Ascraeus, Arsia, and Pavonis Montes, as well as a low shield volcano (Albus Mons) and numerous smaller shield volcanoes (**Figure 5**). 'Shield' volcanoes are so

named because they are characterized by shallowly sloping flanks (4°–11°) that, in profile, look like a Viking shield resting on its handle. The shields within the Tharsis region are morphologically similar to terrestrial shield volcanoes (such as Mauna Loa volcano, Hawaii), complete with summit caldera complexes and volcanic rift zones, but are orders of magnitude larger than terrestrial volcanoes. This size difference is likely because Mars does not have plate tectonics, and so, the lithosphere is never moved away from the underlying melt source. The Elysium region contains Elysium Mons and a number of smaller shields. By analogy with terrestrial basaltic shield volcanoes, it is assumed that these martian shields were fed by an underlying mantle plume (on Earth, a 'hot spot').

In contrast, the volcanoes of the circum-Hellas region have flank slopes even shallower than shield volcanoes (<2°), and their flanks are dissected by radial channels. (Note that prior to 2010, these volcanoes are referred to in the literature as 'paterae'; after 2010, 'patera' refers to the summit caldera complexes of these low-lying volcanoes and the volcanic constructs are called 'montes' (IUGG).) As a group, the volcanoes around Hellas are also called 'highland patera' (Greeley and Spudis, 1981) because they are located in the southern highlands. The low flank slopes and the easily eroded nature of the shield materials have led to the suggestion that these volcanoes experienced explosive eruptions and that the shields are composed primarily of pyroclastic materials (e.g., Crown and Greeley, 1993; Greeley and Crown, 1990). Modeling results suggest that the observed distribution of shield materials could be generated by either explosive decompression of magmatic gases or magma–water–ice interactions as rising magma encountered ground ice or groundwater (Greeley and Crown, 1990; Gregg and Farley, 2006). Impact crater size–frequency distributions and stratigraphy indicate that the explosive activity is ancient (>3.5 Ga) (Williams et al., 2007, 2008). Younger lava flows (as young as ~1.5 Ga) were subsequently erupted from both Hadriacus and Tyrrhenus Montes (Werner, 2009; Williams et al., 2007, 2008). Thus, these volcanoes experienced a change in their volcanic styles with time. Unlike the Tharsis and Elysium regions, the circum-Hellas volcanics may be directly related to the formation of the Hellas basin (e.g., Crown and Greeley, 1993; Greeley and Crown, 1990): it is possible that deep fractures generated by the impact event, combined with mantle upwelling in response to lithospheric thinning, may have created preferred pathways for magma to reach the surface.

Volcanic plains are widespread on Mars (Greeley and Guest, 1987; Scott and Tanaka, 1986) and are interpreted to be composed of low-viscosity basalts (cf. Greeley et al., 2005). Head et al. (2002) proposed that in addition to the visible plains material, there are volcanic plains underlying most (if not all) of the northern lowlands. The type example of these volcanic plains on Mars is Hesperia Planum (**Figure 6**), characterized by a flat surface lacking obvious vents and lava tubes/channels and deformed by wrinkle ridges. Morphologically, volcanic plains are most similar to terrestrial flood basalts. Globally, these volcanic plains are ancient, emplaced prior to about 3.5 Ga (Werner, 2009).

Impact crater size–frequency distributions strongly support that most volcanism on Mars is ancient: the major volcanoes were close to their present size by 3.6 Ga (Werner, 2009). Determining whether volcanism on Mars remains 'active' depends entirely on the definition of 'active.' Terrestrial volcanoes are considered to be active if they have erupted in the past 10 000 years, based on the easily observed evidence left by retreating glaciers at that time. There is no similar standard for Mars. However, lava flows that are as young as 1 Ma have been identified (Hauber et al., 2011) through mapping and impact crater size–frequency distributions.

Evidence for lava–water interactions on Mars remains sparse and elusive, although the planetary conditions would favor these interactions in the past (Head and Wilson, 2002). Lava flows with thermal fracture patterns called 'columnar jointing' have been observed in impact crater walls (Milazzo et al., 2009); on Earth, the formation of columnar jointing is enhanced by the presence of meteoric water (Grossenbacher and McDuffie, 1995). Rootless cones on Earth form when basaltic lava flows over water-saturated ground, and these have been suggested to exist on specific martian lava flows (Fagents et al., 2002). Flank slopes of small (<50 km basal diameter) martian shields increase poleward, and Garvin et al. (2000) suggested that magma interaction with groundwater or ground ice was responsible for the poleward morphological shift. Allen (1979) and Hodges and Moore (1994) used photointerpretation of Viking Orbiter images to identify constructs on Mars that are similar to those formed by subglacial basaltic eruptions on Earth. Gregg et al. (2007) suggested that fluid lavas within Gusev crater (Greeley et al., 2005) ponded against an ice-rich deposit that has subsequently been removed. Chapman (2002) argued that layered mounds within Vallis Marineris were generated by subglacial eruptions. In spite of evidence for glaciers on the flanks of the Tharsis region volcanoes in the past (e.g., Fastook et al., 2008), unequivocal evidence for lava–ice interactions there remains elusive.

10.09.5 Venus

Venus is almost the same size and bulk density as Earth (**Table 1**). Notably, the surface of Venus has an average temperature of ~450 °C and a pressure of 9.6×10^6 Pa at mean planetary radius; the atmosphere is mostly CO_2. There is no evidence for water vapor in the atmosphere (e.g., Donahue and Russell, 1997) and liquid water is unstable at Venus' surface; it is likely that the Venusian lithosphere and interior are also anhydrous (Kaula, 1990, 1995; Phillips et al., 1997). The dry nature of Venus' geologic materials influences their mechanical and physical properties (e.g., Lenardic et al., 1995; Phillips et al., 1997). It may be the lack of water on Venus that is largely responsible for the differences in tectonic and volcanic behavior on Earth and Venus. The limited information available for the composition of the Venusian surface comes from modeling results, measurements made by the Venera landers, and inferences based on volcanic morphology (e.g., Baker et al., 1992, 1997; Gregg and Greeley, 1993; Nimmo and McKenzie, 1998). Overwhelmingly, the evidence points to basaltic volcanism, but there are local exceptions (discussed in the succeeding text).

To understand the scientific context of Venusian tectonism and volcanism, it is necessary to grasp the following concepts: First, there is a lack of impact craters on the surface of Venus

(only 967 on the entire planet (USGS Astrogeology Branch, 1998)), indicating that the average surface age is ~750 Ma (McKinnon et al., 1997). Second, there remains a controversy about the mechanisms responsible for such a young surface. Venus does not have plate tectonics, and so, that cannot be the resurfacing mechanism (e.g., McGill et al., 2010). Two end-member hypotheses have been proposed to explain Venus' young surface: (1) catastrophic resurfacing and (2) equilibrium resurfacing (e.g., Basilevsky et al., 1997; Phillips et al., 1992; Strom et al., 1994). In catastrophic resurfacing, the entire surface of Venus is reformed in one fell swoop, possibly through global lithospheric overturn. In equilibrium resurfacing, volcanism and tectonism act throughout space and time to pave a little bit of the surface with lava here and deform a bit of the surface through tectonism there; over time, the entire planet is eventually resurfaced. Regardless, Venus has a geologically young surface compared to Mars, the Moon, and Mercury.

This begs the question: Is Venus 'active' volcanologically or tectonically? The data available for the Venusian surface were collected by synthetic aperture radar (SAR) or by Earth-based radar to see through Venus' optically thick cloud cover. The resolution of the Magellan spacecraft's SAR instrument was, at best, 75 m per pixel (Wall et al., 1995; Young, 1990); Earth-based radar is on the order of ~2 km per pixel. The Magellan mission collected data from X to Y. During that time, at the best available resolutions, no observable change was detected on the surface. However, the European Space Agency craft Venus Express is currently orbiting Venus and measuring atmospheric properties. Upon arrival at Venusin 2006, the instruments detected a surge in the amount of atmospheric SO_2, which then decayed over time (Marcq et al., 2013); this is consistent with a volcanic eruption injecting SO_2 into the atmosphere. In the absence of information about changes in surface morphology, however, the hypothesis of active volcanism on Venus cannot be disproven.

10.09.5.1 Venus Tectonism

The following tectonic terranes have been identified on Venus: (1) plains, (2) volcanic rises, (3) crustal plateaus and tesserae, (4) coronae, and (5) chasmata (canyons) (**Figure 7**; Hansen et al., 1997; McGill et al., 2010). In the absence of plate tectonics, most of these features are explained by either mantle upwelling, downwelling, or some combination of the two.

Plains are stratigraphically superposed on other tectonic terranes and so are locally the youngest materials. They are interpreted to be volcanic plains, composed of thinly layered lava flows; this interpretation is supported by images of the Venusian surface taken by the Venera landers (e.g., Garvin et al., 1984; Surkov et al., 1983). Plains are typically deformed by wrinkle ridges, graben, lineaments, and/or polygonal lineaments. Although lineaments are not tectonic landforms per se, they are locally, at least, likely to be expressions of a small (subresolution) structural feature such as a fracture or fault. Wrinkle ridges on Venus, imaged by radar, look different from those on the other planets: Magellan SAR cannot resolve a broad arch and a superposed sinuous ridge. Instead, wrinkle ridges are expressed by a sinuous bright line (**Figure 8**; note that Magellan images are processed so that bright = high radar backscatter) and are interpreted to represent compressional forces. Commonly, parallel wrinkle ridge sets extend over hundreds to thousands of kilometers, implying a similar stress field over those distances.

Only graben at least 225 m wide can be resolved on the highest-resolution Magellan SAR data; it is inferred that where graben are found parallel with lineaments, the lineaments are also graben but are too small to be completely resolved. Graben and lineaments in radiating swarms, or nova, are abundant on Venus (Head et al., 1992). Based on their morphological similarities to radiating dike swarms on Earth, the Venusian novas are interpreted to be the surface manifestation of radiating dike swarms that did not quite reach the

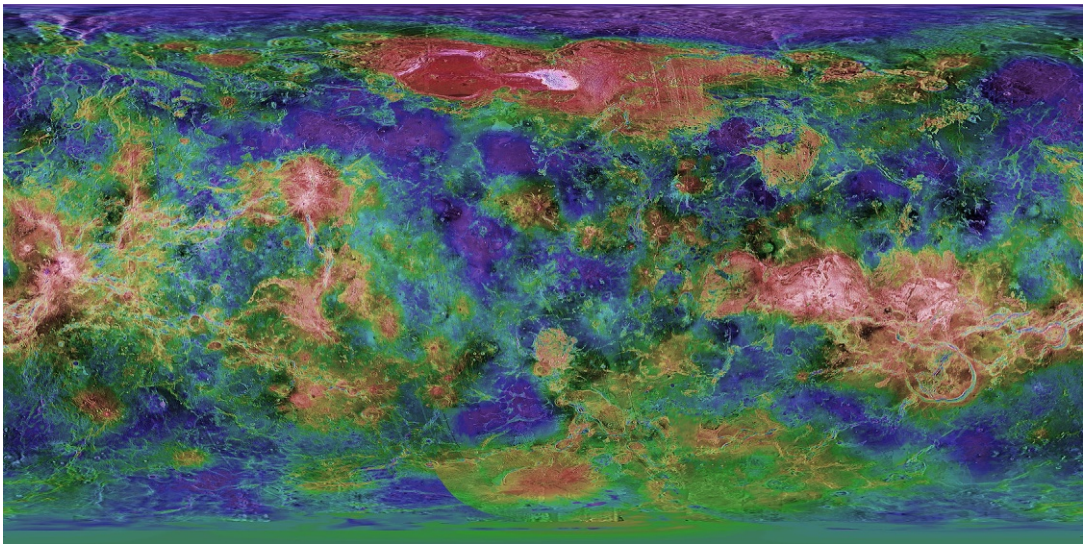

Figure 7 Global Venus topography and SAR. All Magellan images are processed so that bright = high radar backscatter; dark = low radar backscatter. Pinks and whites are topographic highs; blues are lows. (see http://astrogeology.usgs.gov/search/details/Venus/Magellan/RadarProperties/Colorized/Venus_Magellan_C3-MDIR_ClrTopo_Global_Mosaic_6600m/cub).

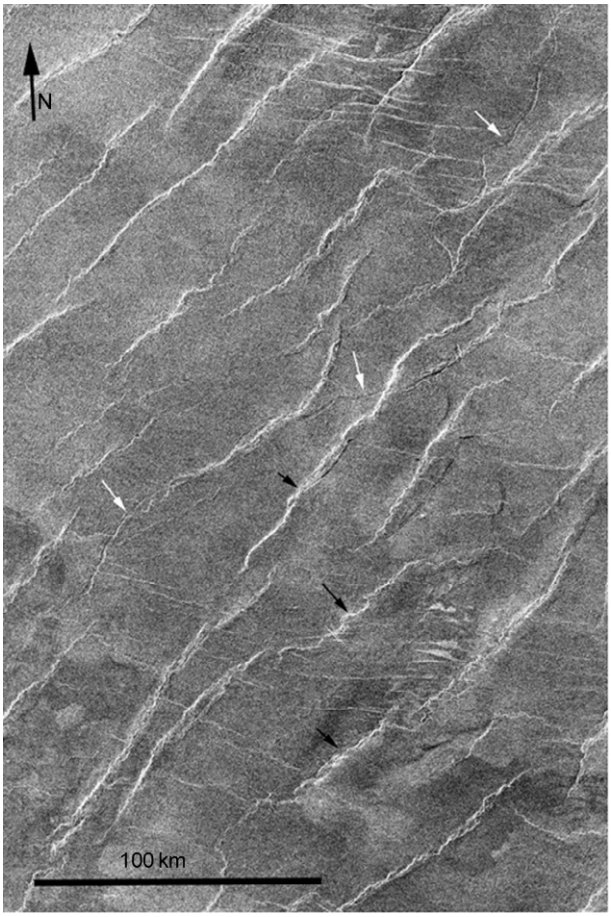

Figure 8 Wrinkle ridges (black arrows) on Venusian plains; image centered at 172° E, 34° S. A sinuous volcanic channel is marked by the white arrows. Image courtesy of NASA/JPL; rendered using mapaplanet.com.

surface to erupt (Grosfils and Head, 1994). Similarly, most of the graben on Venus are interpreted to be the expression of near-surface volcanic dikes (McGill et al., 2010).

Locally, plains are deformed by polygons. These may be constructed of wrinkle ridges (compression) or graben (extension) or of fractures; individual lineaments are commonly too narrow to resolve completely. The precise origin of these polygons remains unclear.

Ridge belts (formally known as 'dorsa') are concentrated zones of compressional deformation within plains materials. They are characterized by a broad (10^2 km) topographic arch, superposed with wrinkle ridges and locally folds (e.g., Banerdt et al., 1997; Zuber, 1990). With one exception (McGill et al., 2010), ridge belts are older than the surrounding plains. Fracture belts are also characterized by a broad topographic arch containing fractures and graben and so are concentrated zones of extensional deformation. They appear to be composed of deformed plains materials.

Ten volcanic rises have been identified to date on Venus, which are 1400–2500 km across, are topographically high (0.5–2.5 km tall), and are spatially associated with some of the largest volcanoes on Venus. Volcanic rises are interpreted to form over mantle plumes, based on topography and gravity data (Phillips and Malin, 1983; Senske et al., 1992); the large compensation depths of some volcanic rises may indicate they are still being actively supported (Smrekar, 1994).

Tessera and crustal plateaus are both topographically higher than the surrounding materials and are older than the surrounding plains. Crustal plateaus are roughly circular regions 1000–3000 km across that are 0.5–4 km above the adjacent plains, and most contain tessera terrain (Hansen et al., 1999; McGill et al., 2010). Compared with volcanic rises, they have shallow apparent compensation depths, suggesting isostatic compensation (McGill et al., 2010). They formed via mantle upwelling (Grimm and Phillips, 1991; Phillips et al., 1991) or downwelling (Bindschadler and Parmentier, 1990; Lenardic et al., 1995). Ishtar Terra is a unique expression of a crustal plateau on Venus (Hansen et al., 1997): it is a large central plain (containing volcanic calderas) surrounded by mountain belts and Maxwell Montes, the tallest mountain on Venus (Bindschadler et al., 1992; Hansen et al., 1997; Keep and Hansen, 1994; Roberts and Head, 1990; Smrekar and Solomon, 1992).

According to the Gazetteer of Planetary Nomenclature (http://planetarynames.wr.usgs.gov/DescriptorTerms), tesserae are 'tile-like, polygonal terrain' but this description does not fully encompass the complicated nature of Venusian tesserae. Tesserae are characterized by multiple intersecting sets of linear to arcuate tectonic features and a high surface roughness relative to the surrounding plains materials (Hansen et al., 1999). Locally, tesserae terrains are the stratigraphically lowest materials, but that does not require that globally all tesserae are the same age (cf. McGill et al., 2010). Given the range of tectonic features and their orientations found in deforming tesserae, it is likely that different patches of tessera represent different episodes of deformation and possibly distinct starting materials (Hansen and Willis, 1996).

Coronae are circular to ovoid features (Basilevsky et al., 1986) 50–260 km across (Glaze et al., 2002) that are typically surrounded by concentric ridges and fractures. Most coronae display volcanic processes: they may contain volcanoes and/or lava flows. They are interpreted to be caused by buoyant mantle material (Hansen, 2003; Smrekar and Stofan, 1997; Stofan et al., 1991) rising from shallower depths than those plumes associated with volcanic rises. Interestingly, coronae are not randomly distributed across the planet, but are concentrated in the Beta–Atla–Themis region (**Figure 9**; Squyres et al., 1993) and tend to be spatially associated with canyon systems (chasmata).

Chasmata are canyons, interpreted to be tectonic rifts. They are <7 km deep and 10^2–10^3 km long (Solomon et al., 1992). The chasmata contain multiple lineaments that can crosscut and extend beyond the rift; although most lineaments are too small to resolve, locally one can be identified as a trough and so all these lineaments are interpreted to be graben or normal faults (McGill et al., 2010). Individual features, such as impact craters (**Figure 10**; Solomon et al., 1992) and volcanoes (Stofan et al., 2005), have been rifted apart by chasmata, allowing for extension to be measured: 10–20 km locally (Connors and Suppe, 2001; Rathbun et al., 1999; Solomon et al., 1992).

10.09.5.2 Volcanism on Venus

The majority of central-vent volcanoes can be identified as shield volcanoes. Crumpler et al. (1997) had classified shield

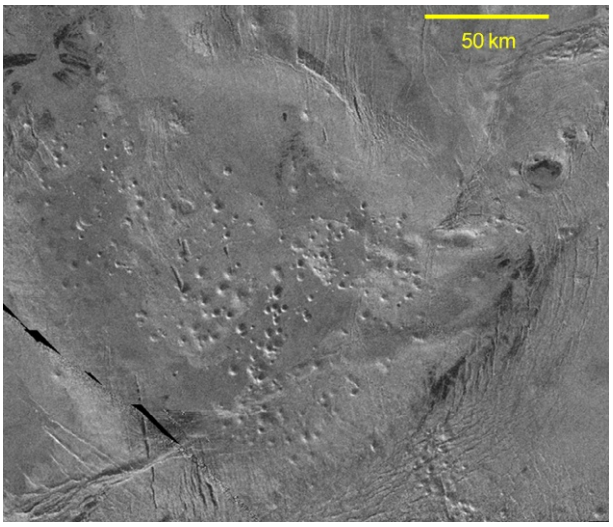

Figure 11 A typical shield field on Venus. Image centered at 78.4° S, 43° E; north is at the top. There are thousands of these fields on Venus. Image courtesy of NASA/JPL/LPI (http://www.lpi.usra.edu/publications/slidesets/venus/slide_26.html).

volcanoes as large (>100 km basal diameter), intermediate, or small (<20 km basal diameter). In addition, there are volcanic features on Venus that are unique among the terrestrial planets.

The most abundant volcanic feature on Venus is small (<25 km basal diameter) shields (Figure 11). There are 10^5–10^6 small shields on Venus, and they typically occur in clusters or groups. Individual shields may contain summit pits. Aubele (2009) had identified two different types of shield clusters: shield fields and shield plains. Shield fields are typically 10^2 km across and contain 10^2 shields, whereas shield plains are 10^3 km across and contain 10^3 shields (Aubele, 2009; Miller and Gregg, 2012). Lava flows from shield fields

commonly bury surrounding wrinkle ridges, but locally lineaments crosscut shields.

Canali are long ($>10^2$ km) sinuous channels found on the Venusian plains and tend to have neither obvious source regions nor sinks. Balta Vallis is the largest example on Venus and is >7000 km long. Along its length, Balta Vallis maintains a consistent width of 3–5 km. The examination of the topography along its length reveals undulations (e.g., Baker et al., 1997) that must have deformed the channel after its emplacement. Long lava flows (10^3 km long) have been identified on the flanks of large shield volcanoes. For comparison, the longest unconfined lava flow yet identified on Earth is the 160 km long Undara flow in Queensland, Australia (see Stephenson et al. (1998) and references therein). (The Grande Ronde flow of the Columbia River Basalts traveled >1000 km from its source, but the lava was confined in a steep and narrow canyon (Mangan et al., 1986).) Many scientists have questioned whether typical tholeiitic basalts could flow such great distances without solidifying, even on Venus, and have therefore considered the possibility of more exotic lava compositions with low melting temperatures and low viscosities (such as carbonatite and sulfur) (e.g., Gregg and Greeley, 1993; Kargel et al., 1994). The main difficulty with the exotic lava hypothesis is that it is untestable: models of flow behavior confirm that carbonatite or sulfur flows could flow hundreds to thousands of kilometers without solidifying, but petrologic models cannot generate the 10^5 km^3 of exotic lavas required to fill the observed channels on Venus. Without more constraints on the composition of Venus, the likelihood of large volumes of exotic lavas cannot be assessed.

Valley networks observed on Venus must be the result of volcanic processes because liquid water cannot exist at the Venusian surface. Baker et al. (1992, 1997) and Komatsu et al. (2001) classified valley networks based on morphology as simple (e.g., canali), complex, compound, or integrated. Valley networks are found in plains materials and may be the source of lava comprising the plains. Some simple valley networks are morphologically similar to lunar sinuous rilles and probably have similar origins. The complex and compound valley networks, consisting of many tributaries, distributaries, and anastamosing reaches, can only be formed by a long-lived (months to centuries) eruption (Gregg and Greeley, 1993). Integrated networks are morphologically similar to valley systems generated by groundwater sapping processes on Earth; they appear to have been formed by collapse caused by subsurface removal of material. On Venus, integrated networks may form as lava tube roof collapse or may represent the presence of a low-viscosity, low-melting-temperature lava on Venus, such as carbonatite or sulfur flows (e.g., Baker et al., 1992, 1997; Kargel et al., 1993; Komatsu et al., 2001).

At the other rheological extreme are 'pancake domes' (**Figure 12**), which are steep-sided, flat-topped volcanoes >20 km across and <5 km tall. Some contain a summit pit. They typically occur in groups and are aligned, suggesting that they were emplaced via a dike. Their large aspect ratio (diameter/height) is similar to the aspect ratio of silica-rich (rhyolite) domes on Earth, such as the Inyo domes in Long Valley, California (Stofan et al., 2000). This observation led to the interpretation that the Venusian domes may also be rhyolitic or at least contain more SiO_2 than typical basalts. The Soviet lander Venera 13 returned measurements of the surface composition consistent with alkali basalts, a type of basalt more evolved than tholeite. Pancake domes are located within the Venera 13 landing elipse (Weitz and Basilevsky, 1993), and it is possible that Venera 13 touched down on top of one of these domes. However, the Venusian domes are 10–100 times more voluminous than terrestrial rhyolite domes, and the petrogenesis of such large quantities of evolved magma in the absence of water or plate tectonics is uncertain. More importantly, detailed analyses of surface roughness and dome topography on Earth and Venus suggest that the Venusian domes are unlike terrestrial silica-rich domes (Stofan et al., 2000).

10.09.6 Mercury

Mercury, slightly larger than Earth's Moon (**Table 1**), has the largest iron core relative to planetary radius of all the terrestrial planets. It is also the closest to the Sun, and 'space weathering' (the interaction of solar ions with Mercury's surface) affects the physical properties of surface materials in ways that are not yet fully understood (e.g., Robinson et al., 2008; Zurbuchen et al., 2008). It lacks plate tectonics and is a 'single-plate' planet like the Moon and Mars. In 1974–75, Mariner 10 made 3 flybys of Mercury and succeeded in mapping almost 45% of the planet at a resolution >1 km per pixel. NASA launched the MERcury Surface, Space ENvironment, GEochemistry, and Ranging (MESSENGER) spacecraft in 2004, and as of this writing, it is in orbit around Mercury (see http://www.nasa.gov/mission_pages/messenger/main/index.html), and almost the entire surface has been imaged at resolutions >250 m per pixel.

10.09.6.1 Mercury Tectonics

Tetonic features on Mercury can be broadly categorized as being either 'impact basin-related' or 'distributed' (Watters and Nimmo, 2010; Watters et al., 2009a). The Caloris basin (**Figure 13**) is the largest feature on Mercury and displays one main topographic ring with a diameter of 1550 km. Additional concentric features have been mapped both inside and outside the main ring (Murchie et al., 2008), and these may be additional basin rings. The Caloris basin displays a range of tectonic features that represent 'basin-related' tectonics on Mercury (e.g., Watters et al., 2009b).

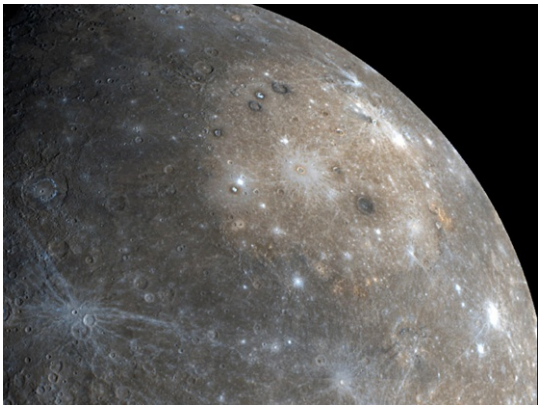

Figure 13 The Caloris basin is the light-colored circular feature near the center of the image and is ~1550 km across. MESSENGER imaged all of Caloris for the first time in 2008. Image courtesy of NASA (http://science.nasa.gov/science-news/science-at-nasa/2008/01oct_mercuryflyby2/).

Tectonic features observed on Mercury include wrinkle ridges, lobate scarps, high-relief ridges, and troughs (interpreted to be graben). Compressional features are far more abundant than extensional ones (Watters and Nimmo, 2010) and are consistent with global contraction (possibly related to the formation of the large iron core). Crosscutting relations suggest that most lobate scarps formed after the emplacement of the smooth plains materials and infilling of Caloris and Rembrandt basins (Solomon et al., 2008; Watters et al., 2005, 2009a) and may be related to local loading (possibly infilling of impact craters with lava).

Lobate scarps are the most common tectonic feature on Mercury (Watters et al., 2009a) and, like those on the Moon and Mars, are interpreted to be thrust faults (**Figure 14**; Nimmo and Watters, 2004; Watters and Nimmo, 2010). They are considered to be 'distributed' and have been observed to crosscut exterior basin fill materials associated with the Caloris basin (cf. Watters et al., 2009b). The oldest materials deformed by lobate scarps are intercrater plains (>4.0 Ga) (Spudis and Guest, 1988; Watters et al., 2009a), and the youngest materials that lobate scarps crosscut are less than ~3.5 Ga old, placing rough constraints on the timing for these features. On Mercury, each lobate scarp represents 1–3 km of shortening (Watters et al., 2009c). The longest lobate scarp yet identified is Enterprise Rupes (centered at 36.5° S, 283.5° W), which is at least 1000 km long (Watters et al., 2009c). Topographic relief across lobate scarps ranges from 0.9 to 2.0 km. Based on the measurements of fault scarp heights and the modeling of thrust fault behaviors, the estimate for Mercury's T_E at time of faulting was on the order of 35–40 km (Watters et al., 2002); recent measurements using the MESSENGER Mercury Laser Altimeter (Cavenaugh et al., 2007) allowed Zuber et al. (2010) to estimate values as high as 60 km for Mercury's T_E.

Wrinkle ridges on Mercury are morphologically similar to those observed on Mars (e.g., Head et al., 2008; Solomon et al., 2008; Strom et al., 1975) (**Figure 15**); even ridge rings (which form over buried impact crater rims) have been identified (Watters and Nimmo, 2010; Watters et al., 2009a). Wrinkle ridges tend to be found in topographic lows and may therefore be related to basin subsidence (Watters 1988, 1993). Importantly, every type of smooth plains yet identified on Mercury (both those interpreted to be volcanic and those interpreted to be impact-related) is deformed by wrinkle ridges (Watters et al., 2009a).

Unlike wrinkle ridges, high-relief ridges are symmetrical in profile and have up to 2.0 km of topographic relief; they can locally transition into lobate scarps. They were first observed in Mariner 10 images and are so-called because they were

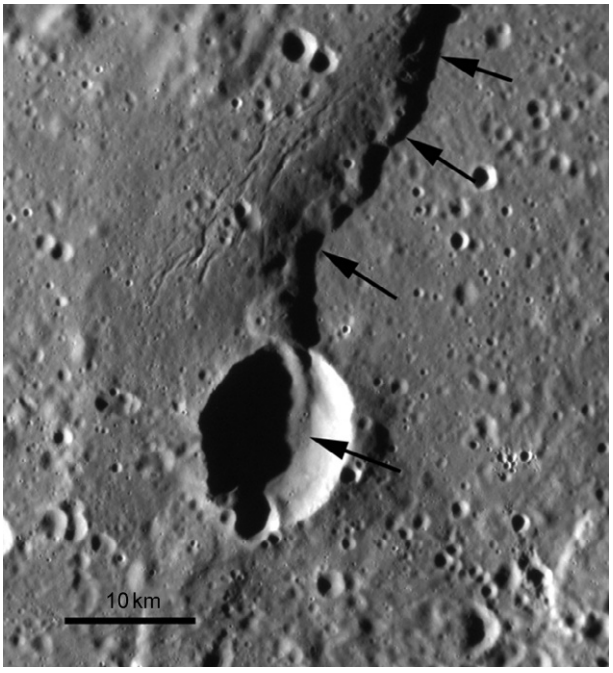

Figure 14 Lobate scarp (black arrows) on Mercury; note that the lobate scarp crosscuts the 12 km diameter impact crater near the center of the image. Image centered at 7.8° N, 151.1° E. MESSENGER narrow-angle camera image courtesy of NASA/JHU/JPL (see http://messenger.jhuapl.edu/gallery/sciencePhotos/pics/Wednesday_September_11.jpg).

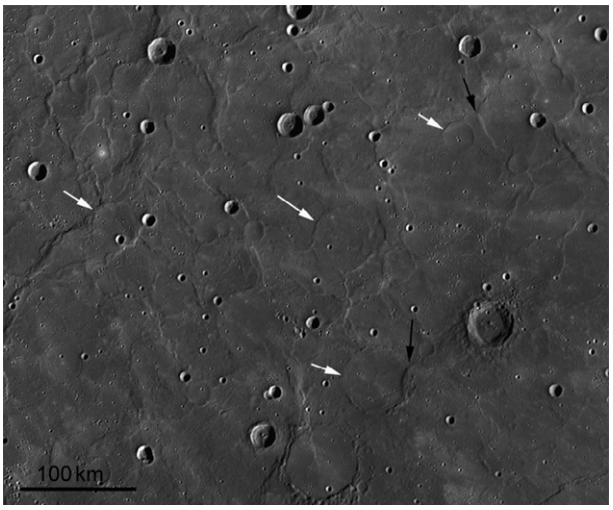

Figure 15 Ridge rings (white arrows) and intersections of wrinkle ridges (black arrows) on Mercury. Image centered at 55.3° N, 32.5 °E. Mercury Dual Imaging System image courtesy of NASA/JHU/APL.

described as ridges with 'significant relief' in the intercrater plains (Dzurisin, 1978). Like wrinkle ridges, high-relief ridges are found within intercrater plains and appear to have formed at approximately the same time as wrinkle ridges (Watters and Nimmo, 2010). Although these features are high-relief, they are only visible in low-sun-angle images or in Mercury Laser Altimeter data (Solomon et al., 2008; Watters et al., 2009a). These observations suggest that high-relief ridges are high-angle reverse faults.

Extensional features are rare on Mercury and were only identified in the eastern half of the Caloris basin from Mariner 10 data (Strom et al., 1975). As of this writing, MESSENGER images reveal linear to arcuate troughs, interpreted as graben, associated with two of the largest impact basins (Caloris and Rembrandt) and three intermediate-sized basins (Raditladi, Rachmaninoff, and Mozart) (Byrne et al., 2013). Caloris contains radial and concentric graben (Murchie et al., 2008; Watters et al., 2009b); Raditladi basin (255 km diameter; 27° N, 119° E) contains concentric graben; and Rembrandt basin (700 km diameter; 33° S, 88° E) contains radially oriented fractures and troughs.

Caloris basin contains Pantheon Fossae (**Figure 16**), a swarm of radiating troughs or graben (Murchie et al., 2008; Solomon et al., 2008; Watters et al., 2009b). On Earth, radiating graben are formed when a mantle plume or diapir impinges on the lithosphere, causing uplift and intrusion of radial dikes (e.g., Ernst et al., 1995); graben form above the rising dikes. By analogy, Pantheon Fossae and the extensional features observed in Rembrandt and Raditladi basins are interpreted to be the result of magmatic uplift sometime after basin formation (similar to floor-fractured craters on the Moon; Wichman and Schultz, 1995). Alternatively, the emplacement of volcanic plains materials outside of the basin may have locally loaded the lithosphere, causing flextural uplift – and resulting extension – in the basin interior (Melosh and McKinnon, 1988). Watters et al. (2005, 2009b) supported lateral flow of the lower crust toward the basin interior, caused by differences in elevation and crustal thickness.

Interestingly, morphologically similar trough (interpreted to be graben) swarms have been identified in Mercurian volcanic plains (Watters et al., 2012b) and are found within wrinkle ridge rings. These swarms, combined with ridge rings, are interpreted to mark the locations of buried impact basins. The juxtaposition of graben encircled by compressional wrinkle ridges likely resulted from a combination of extensional stresses (cooling and thermal contraction of the plains materials) and compressional stresses (related to cooling and contraction of Mercury's interior (Watters et al., 2012b).

10.09.6.2 Mercury Volcanism

Unlike the other terrestrial planets, volcanic edifices are rare on Mercury. Head et al. (2008) characterized a possible volcanic shield volcano within Caloris basin (see also Murchie et al., 2008); Prockter et al. (2010) identified a likely volcanic vent within Rachmaninoff basin (290 km diameter; 28° N, 58° E). Hurwitz et al. (2013) identified possible lava channels on Mercury, although it is not clear if they are constructional or erosional features. The dominant expression of volcanism on Mercury, however, appears to be volcanic plains (Denevi et al., 2013; Head et al., 2008).

Head et al. (2008) examined data collected on Caloris basin from the first MESSENGER flyby and identified volcanic vents and deposits along the southern margin of the interior of the Caloris basin (**Figure 17**). For example, they pointed to a 'kidney-shaped' depression about 20 km long surrounded by relatively a relatively high-albedo deposit covering a roughly

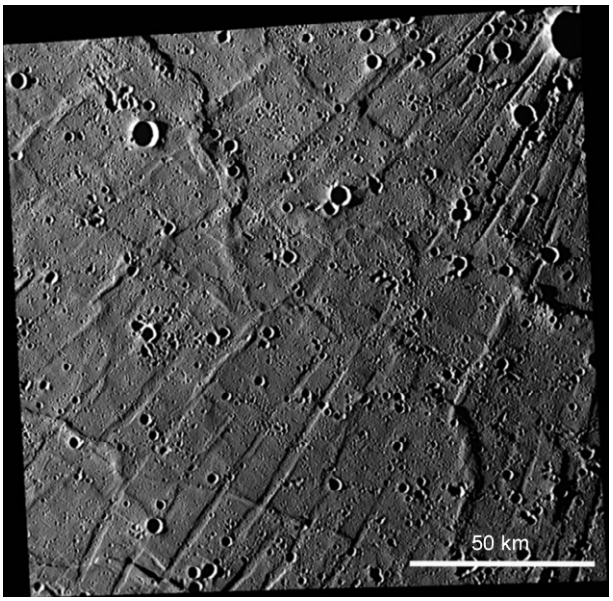

Figure 16 A portion of Pantheon Fossae, one of the few extensional networks on Mercury. Image centered at 25.2° N, 158.9° E. Image acquired by the Mercury Dual Imaging System wide-angle camera; image ID 2213443. Image courtesy of NASA/JHUAPL (see http://messenger.jhuapl.edu/gallery/sciencePhotos/pics/EW0250969390G.map.web.png).

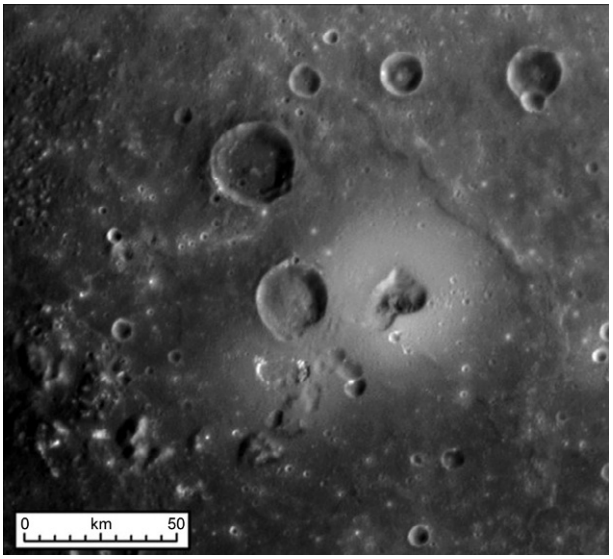

Figure 17 Likely volcanic vents (irregularly shaped depressions in the left of the image) within the rim of Caloris basin. Image centered at 22.0° N, 146.4° E. Image courtesy of NASA/JHUAPL (see http://science1.nasa.gov/media/medialibrary/2008/07/03/03jul_mercuryupdate_resources/kidney.jpg).

circular area up to ~50 km from the depression. They interpreted this to be a volcanic construct (Prockter et al., 2010). Smooth plains materials in and around Caloris basin are also interpreted to be volcanic (Murchie et al., 2008); recent studies (Ernst et al., 2013; Klimczak et al., 2013) suggest that the volcanic fill within the Caloris basin is about 2.5–4.0 km thick.

There is a strong morphological similarity between smooth plains deformed by wrinkle ridges on Mercury and on Mars: both planets display intersecting wrinkle ridges systems and ridge rings (**Figure 15**; Head et al., 2008). The morphological similarities between lunar mare-type wrinkle ridges (found only in the mare basalts), martian wrinkle ridges, and mercurian wrinkle ridges support the interpretation that many of the plains on Mercury are volcanic (Denevi et al., 2013).

10.09.7 Summary

The Earth is the only planetary body in the solar system that displays 'plate tectonics,' although Mars may have experienced Earth-like seafloor spreading briefly shortly after planetary formation. In the absence of plate tectonics, the other planetary bodies of the inner solar system display faults and fractures formed by impact- or volcanic-induced stresses or by more global stresses associated with core formation and cooling. Mare-type wrinkle ridges, first identified and characterized on the lunar basalts, are near-surface thrust faults and are the most abundant tectonic feature in the inner solar system.

Volcanism in the inner solar system is dominated by basalt. This is the case even on Earth, where the entire ocean floor is composed of basaltic lava flows. Volcanic behaviors differ widely on the terrestrial planets, from enormous shield volcanoes on Mars to dark mantling deposits on the Moon. The longest channel in the solar system is a lava-formed channel on Venus: Baltis Vallis is longer than the Earth's Nile River.

As we encounter these volcanic and tectonic extremes, it is essential to remember that Earth provides us with only one datum as we seek to understand the processes that shape our world. Only by examining and understanding volcanism and tectonism throughout the solar system can we be truly sure we understand how those processes operate at home.

10.10.1 Introduction

Exogenic dynamics of planets (in contrast to endogenic dynamics) refers to externally generated dynamical processes, and here, we discuss specifically the exchange of material between the different zones of the solar system and the effects when this material interacts with the surface of a solid planetary body. Material can be transported due to the gravitational perturbation of planets acting on the material rotating around the Sun. This material reaches the solid surface of a planet with high velocity, which ranges from a few km s^{-1} up to 100 km s^{-1}, when their orbits cross each other. If the mass difference is large, the gravitational attraction of the larger body assists in modifying the orbit and it can raise the collision probability under a near-encounter (gravitational focusing). The collision with the planetary solid surface (or with a planetary atmosphere) decelerates the falling body (the *projectile*), converting its kinetic energy into potential energy, heat, light radiation, and shock waves and creating cavities – impact craters – at the surface of the struck planets. High-velocity impacts redistribute ejected material; create a temporary *hot spot* in the crust, melt, fracture, demagnetize rocks; displace them; and sometimes eject a small portion of rocks out of the planet's gravity field. The ejecta can reach another planetary body, providing material exchange between planets. Currently, we find Martian (Martian meteorites belong to a group with the historical abbreviation SNC named after shergottite, nakhlite, and chassignite, now recognized as rocks from Mars (Wood and Ashwal, 1981)) and lunar meteorites, as well as asteroidal fragments, such as the HED meteorites, on Earth. (HED, which stands for

howardite, eucrite, and diogenite that are considered to have originated from the asteroid 4 Vesta (McCord et al., 1970).) The impact site can be modified subsequently, for example, by readjustment due to gravity of impact craters, cooling of impact melt body, or general geologic activity. The modification depends on the size of the planet, its mechanical and thermal structure, and the size of the impact event. The most significant difference between impact site modification in the early stages of planetary evolution and today relates to the cooling of the terrestrial planets with time.

The efficiency of the exogenic dynamics and modification rate of planetary surfaces depend on the frequency of impacts of a given energy and the geologic evolution of the impact site. The frequency of impacts is coupled to the power of the small-body sources and the efficiency of small-body delivery to the target planet. Both parameters did evolve, being different in the first 0.5 Ga after the solar system formation (ancient bombardment rate) and today (the modern bombardment rate). The projectile flux evolution is intimately connected to the history of the solar system formation. The current paradigm of the solar system formation starts with the collapse of the protosolar dust–gas nebula and the ignition of the star (Sun) in the center, followed by events that included the accretion of dust, dust/ice, and gas into sizable bodies in a rotating disk, while gas continuously is removed by solar radiation, as discussed in pioneering work by Safronov (1969) and Wetherill (1978, 1980). The dust/ice ratio in growing bodies is probably controlled by the solar insolation, limiting the presence of volatiles close to the heating Sun. This resulted in the formation of protoplanetary bodies with volatile proportion growing with the distance from the Sun, manifested in the formation of more rocky bodies within the modern Jovian orbit with semimajor axis $a = 5.2$ AU (1 AU – astronomical unit – is equal to the Earth–Sun distance of $\sim 1.5 \times 10^6$ km) and protoplanetary bodies with much larger volatile (frozen gases) content beyond that. The feeding zone in the central part of the solar system produced terrestrial planets (Mercury, Venus, Earth, and Mars), their satellites (the Earth's Moon is the biggest), and a swarm of small bodies, asteroids, between the orbits of Mars and Jupiter by mutual collision and accumulation events of preplanetary small bodies (planetesimals). The processes involved in the growth of planetesimals from dust grains are poorly understood (e.g., Chambers, 2010). Later phases of solar system evolution consider the implications of the giant planets' growth on the terrestrial planet formation and the evolution of the projectile source (e.g., reviewed by Morbidelli et al., 2012a). Jupiter and the other giant planets (Saturn, Uranus, and Neptune) accumulated a huge amount of gases before the total dissipation of the gas portion of the disk. A second belt of planetesimals is found beyond the orbit of Neptune, the Kuiper–Edgeworth Belt, which remained due to a combination of too low disk density and too high accretional timescales. The composition of these planetesimals is supposedly consistent with volatile low-temperature condensates formed at large distances from the Sun (reviewed by Brown, 2012).

10.10.2 The Evolution of the Solar System

The view on the evolution of our solar system has become more complex after the discovery of many very different extrasolar planetary systems (e.g., Morbidelli et al., 2012a), and we will try here to evaluate the implications of these more complex evolution schemes on the method of surface-age determination using the impact crater record of solid surface planetary bodies. The early stage of the planetary formation is controlled by celestial mechanics of small bodies revolving around the Sun. The orbits of the small bodies change due to mutual collisions and (possibly) the drag of gaseous disk residuals. Planetary embryos form in a very short time (e.g., Morbidelli et al., 2012a). The growth of a few main planets results in 'excitation' of the orbits of smaller bodies and, possibly, in mixing of individual planetary feeding zones at the end of the main planet formation phase (see **Chapter 10.16**). After the Sun, Jupiter is the most massive and gravitationally important body in the solar system. Due to its significant mass, Jupiter sets up resonance zones that perturb the motion of other planets, small bodies, and their fragments. Beyond Mars, the presence of growing Jupiter exited the orbital motion of local protoplanetary bodies (the origin of natural satellites is discussed in **Chapter 10.17**). Collision velocities increased, fragmentation began to dominate over accretion, and this limited the size of the largest bodies accumulated in this zone, which becomes later the main asteroid belt (MAB). Currently, the largest body in the MAB is Ceres with a diameter of ~1000 km. The formation of larger, for example, Mars-sized, bodies cannot be excluded, and they could have originally been accumulated here or elsewhere among terrestrial planets but removed soon after by the gravitational perturbation of Jupiter and mutual gravitational interaction between the largest protoplanets (Chambers and Wetherill, 2001). The flux of these bodies together with *leftovers* from the feeding zones of the terrestrial planets created the early heavy bombardment of just-formed crusts on terrestrial planets. The timescale of terrestrial planet formation is up to 100 Ma (reviewed by Kleine et al., 2009). The largest MABs (>~100 km in diameter) are most probably leftovers of the primary population, while the smaller ones are probably fragments, formed during the collisional evolution. Some small bodies leave the MAB into planetary-crossing orbits under the action of orbital resonances with Jupiter and Saturn. The motion of planet-crossing bodies also evolves due to weak resonances with Mars and close encounters with the terrestrial planets. The small-body lifetime of a typical planet-crosser is between 1 and 30 Ma (Gladman et al., 2000), and thus, a steady-state flow of bodies supplied from the MAB is required before one of them strikes the surface of one of the terrestrial planets.

The planet accumulation rate is strongly controlled by the period of one revolution about the Sun. At the distance of the Earth, a body makes one full revolution during 1 year. At the distance of Jupiter, it takes 11 years. At the distance of modern Uranus, the revolution period is as large as about 84 years, and for Neptune, about 165 years. Theoretical accumulation rate estimates based on the distance from the Sun result in a mismatch between the formation time of terrestrial planets and too large time for the formation of Uranus in their today's observed position. Therefore, Zharkov and Kozenko (1990) proposed the hypothesis that permits Uranus and Neptune or the formation of their embryos closer to the Sun with following migration to the modern orbits (numerically tested later by, e.g., Masset and Snellgrove, 2001). In addition to an early migration in the gas envelope, the gravitational interaction with massive icy planetesimal disk is considered to be the main engine for

the post-gas giant planet migration (Fernandez and Ip, 1984; Malhotra, 1993; Tsiganis et al., 2005).

The migration of giant planets, as well as their formation (mass concentration appearance), would 'excite' orbits of small bodies, producing an additional *bombardment epoch* for the inner planets and causing the ejection of parts of small bodies far from the Sun (as suggested in the Nice model by a series of publications: Gomes et al. (2005), Tsiganis et al. (2005), and Morbidelli et al. (2005)). Accordingly, 'leftovers' of the giant planet formation shaped the periphery of the solar system: the spherical shell of comets (cometary nuclei, in a strict sense), the Kuiper–Edgeworth Belt beyond the Neptune orbit, and also the Pluto–Charon system. (The Pluto–Charon system, had it been discovered today, would have been cataloged as a member of the Kuiper–Edgeworth Belt (Bertoldi et al., 2006; Sheppard, 2006.) In 2006, Pluto's official status was changed from 'planet' to 'dwarf planet' (Green, 2006; see **Chapter 10.01** for definitions of planets and dwarf planets).) However, the giant planet evolution in our solar system and in extrasolar systems remains unclear (reviewed by Lissauer and Stevenson, 2007) for modern migration models. The giant planets have to form faster than the terrestrial planets (e.g., Morbidelli et al., 2012a). After the possible heavy bombardment epoch, related to the giant planet migration, the small-body population was mixed, and the most icy planetesimals remained beyond the orbit of Neptune. This group of trans-Neptunian objects or further out Kuiper Belt objects (KBO, discussed in **Chapter 10.20**), are occasional returning comet nuclei and KBOs close to the Sun, and create a small-body bombardment population of comets. Comets, spending considerable time close to the Sun, loose most of their volatiles and can become a subpopulation of dormant or extinct comets, which can develop asteroid-like orbits (e.g., Levison et al., 2009). The proportion of active, dormant, or extinct comets in the total bombardment flux on terrestrial planets is a matter of current debates (Fernandez et al., 2002; Stuart and Binzel, 2004), but most of the comets entering the inner solar system are expected to disrupt (Levison et al., 2002). The first version of the *Nice* (Nice after the town in France, where the model was developed) model (Gomes et al. (2005), Tsiganis et al. (2005), and Morbidelli et al. (2005)), with the conceptional idea of giant planet migration, argued for comets from the outer solar system, restricted to the period of the excitation due to the migration as major projectile population for the terrestrial planets during the period of Late Heavy Bombardment (LHB). This idea was conformed to suggestions that the basin-forming projectile population is now extinct (Head et al., 2010; Werner, 2008). However, most recent estimates of one of the derivations of the Nice model suggest that only a minor portion of the projectiles is cometary (Bottke et al., 2012), which is in agreement with the estimates by Ivanov et al. (2002) of <15% of comet impacts for terrestrial planets. The latter point of view has been discussed in a set of papers (Hartmann, 1977; Hartmann et al., 2002; Ivanov, 2001, 2004; Ivanov et al., 2001, 2002) previously. The relative role of various projectile populations is still under investigation.

Despite the general success of the migration/Nice model (now often considered the mainstream), many detailed problems require further investigation. Because these problems are vital for estimates of the 'pre-LHB' bombardment rate, we briefly list selected recent papers. More detailed information on the progressing work on these models is summarized by Michel and Morbidelli (2013). In the basic gas drag/gravity migration model ('Nice I' according to Levison et al., 2011), the migration and the gravitational interaction action of planetesimals are explained by close encounters with giant planets as it was proposed by Fernandez and Ip (1984). One can assume that a few of these planetesimals could reach the inner solar system and raised the pre-LHB bombardment rate in the region of the proto-MAB and terrestrial planets (like modern ecliptic comets, e.g., Levison and Duncan, 1997). Internal problems of the model motivate the expansion of the model components resulting in conceptually new possibilities. Levison et al. (2011) proposed the 'Nice II' model with many innovations. Now, the planet migration is assumed to operate 'remotely' by the gravitational interaction with the outer planetesimal disk as a whole without the necessity of physically close encounters. In this case, the 'comet-like delivery chain' of planetesimals into the inner solar system (as in Levison and Duncan, 1997) may be much smaller than in the 'Nice I' model. Models of cometary flux through the MAB during LHB constrain the 'cometary' fraction but assume the 'death' of comets near to the Sun (Broz et al., 2013). The comprehensive discussion of the early bombardment flux is published by Fassett and Minton (2013).

The other issue of the planet migration models is the 'initial' state of planetary configuration at the time of vanishing of the gas envelope. In the 'Nice II' model, the configuration is assumed from the results of Morbidelli et al. (2007). Other models allow much stronger migration of Jupiter, approaching as close to the Sun as ~1.5 AU during the first 100 000 years (the 'Grand Tack' scenario by Walsh et al., 2011, 2012). The mechanism results in the appreciate mixing of 'dry' and 'wet' material in the inner solar system and is able to facilitate the proper Mars mass in the modeling (see the review by Brasser, 2013).

Another issue discussed is the fine details of the 'Nice event' (the resonance of Jupiter and Saturn). The model mechanism of the LHB is the resonance sweeping through the pre-LHB asteroid belt, which results in the redirection of small bodies toward planet-crossing orbits (Minton and Malhotra, 2009, 2010). The original estimates of the LHB duration and intensity have been found adequate for ~0.5 My characteristic time of the Nice event. However, the Nice model's typical characteristic time is ~5 My (Morbidelli et al., 2010). The reconciliation is proposed in the more complex Nice event scenario, which demands a third giant planet (Uranus or Neptune) to make a close encounter with Jupiter and Saturn, accelerating the Nice event ('jumping-Jupiter' model; Fassett and Minton, 2013; Morbidelli et al., 2010). Additional (now missing) planets are often discussed in the planet formation models to tune the outcome to the real solar system (Brasser et al., 2013; Nesvorný and Morbidelli, 2012).

For satellites of giant planets, comets seem to be most probably the main bombardment population (Zahnle et al., 1998, 2003). However, estimation of absolute impact fluxes for the outer solar system stays an extremely difficult problem at present levels of knowledge, since interplanetary source populations are poorly known. Cratering on the icy satellites of the outer planets is beyond the focus of this chapter. In

general, numerical models of the solar system evolution (n-body simulations) strongly depend on the initial conditions and thus cannot be considered as model-independent evidence.

The authors point out that with the conceptual Nice model, impact flux estimates of absolute ages for the outer solar system could be in the future calibrated using the onset and duration of the LHB period to postulate a solar system-wide event. However, the planet-crossing bodies that might hit or have hit Jupiter and Saturn satellites are still unexplored so that statistics are very poor regarding the size–frequency distribution (SFD) at small sizes. Dynamical methods are compromised because there may be various poorly studied resonant effects throwing objects onto Planetary crossing orbits (PCOs) (as with near-Earth objects (NEOs) from MAB resonances), and the parent populations such as KBOs, Centaurs, and Trojan swarms are not fully characterized. Surfaces such as on Europa, Titan, and parts of Enceladus, with notably small crater densities, are believed to have geologically young absolute ages, indicating ongoing heating and geologic activity, but we believe the error bars on ages must be much larger than the factors 2–4 that have been quoted for Mars. A more complete discussion of the impact cratering and cratering rate on outer planet's satellites is presented, for example, by Kirchoff and Schenk (2010), Schenk et al. (2004), and Zahnle et al. (1998, 2003). A discussion of the bombardment history in the context of the LHB concept is published by Charnoz et al. (2009) and Barr and Canup (2010).

10.10.3 Impact Craters: Morphology

Impact craters are circular depressions with elevated rims (Figure 1) created by the collision of celestial bodies. The impact crater formation occurs as a chain of subsequent processes: it starts with a high-velocity impact and ends with ejected material deposition and crater cavity adjustment to the new equilibrium of fragmented rocks in the planetary gravity field. First observations of impact craters have been done with telescopic observations of the Earth's Moon starting with Galileo Galilei. Impact craters were eventually recognized on the Earth's surface, particularly in the 1950s and 1960s (Dence, 1965; French and Short, 1968). With the beginning of space flights, the scientific interest in craters has grown enormously. Both imaging of extraterrestrial planetary bodies and studying of terrestrial impact craters advanced our understanding of the cratering process. In terms of understanding times and rates of geologic processes on planets, we are fortunate that nature *stamps* sharp, symmetrical circular structures on planetary surfaces. If the crater formation rate is understood, we can estimate ages from crater frequencies and interpret the nature and rates of geologic activity, such as erosion and deposition processes, from morphological degradation and losses of craters.

The close-up imaging of the Moon has revealed the fundamental difference of the impact crater population from other (e.g., volcanic) crater structures, namely, the wide spectrum of crater sizes, continuing from microns to thousands of kilometers.

The size–morphology progression ranges from small, simple bowl-shaped craters, to craters with central peaks and terraces at the walls (an example is shown in Figure 1), up to basins with inner rings and, on some bodies, exterior scarps that encircle the impact site. A collection of papers in the book *Impact Cratering: Processes and Products* (Osinski and Pierazzo, 2013) gives an extended introduction to the impact cratering topic.

The morphological diversity of craters seems not a direct result of the crater excavation process, but develops only as the explosion cavity evolves just after most of the material has been ejected from the initial cavity. The initial product of crater excavation is considered to be a circular, bowl-shaped *transient* cavity with a depth/diameter ratio between 1/4 and 1/3. This transient crater then undergoes different degrees of modification as a result of gravitational instability and collapse of the crater walls and the rebound of the crater floor. The final crater morphology depends on the gravitational acceleration, density, and condition of the surface material of the target planet. This affords both the opportunity of using impact crater morphology to learn about conditions in the target and the challenge of understanding how different conditions affect the course of crater collapse (Melosh and Ivanov, 1999).

Dence (1965) first classified terrestrial impact craters as either simple or complex in structure. This classification,

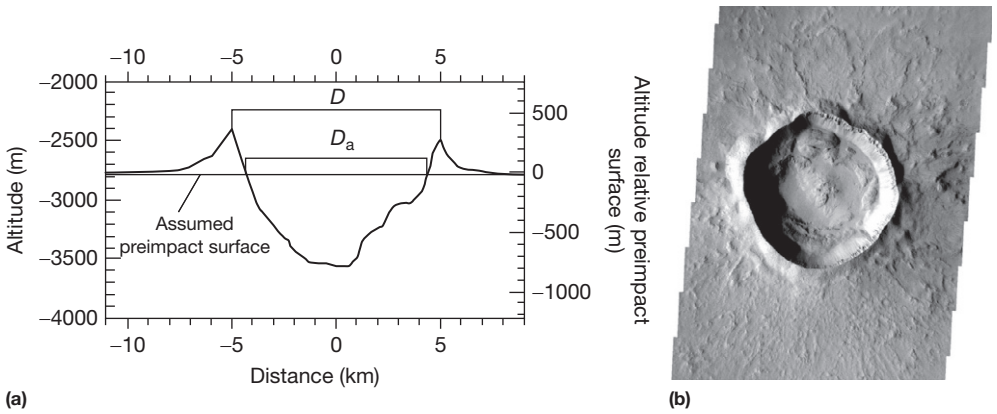

Figure 1 The profile of a typical fresh impact crater (exemplified with the 10 km diameter Martian crater Zunil, profiled by MOLA track, a). This north-to-south profile does not reveal the small central mound visible in high-resolution image (b, THEMIS image V09818024). The figure introduces the often used rim crater diameter, D, and the apparent crater diameter, D_a, measured at the preimpact surface level.

based on the study of craters exposed by erosion, also seems to apply to the morphology of fresh craters revealed by images of the surfaces of other planets and satellites. Data sets on terrestrial and planetary craters are highly complementary: Due to erosion, geophysical investigations, and direct drilling, the subsurface structure of many terrestrial craters can be explored in detail, while the surface morphology is often displayed in exquisite detail by images of fresh craters on the surfaces of other planets or satellites (for a brief review, see Wright et al., 2013).

Simple craters are circular, bowl-shaped depressions with raised rims and approximately parabolic interior profiles. The rim-to-floor depths of a large sample of simple craters on the Moon are roughly 1/5 of the rim-to-rim diameter (Pike, 1977a). Simple craters have a true floor, covered with a breccia lens up to a half of the *true crater* depth. Drilling results and seismic investigations prove that this lens is created by fragmented material avalanched from the transient crater walls down into the crater, forming the *apparent* crater floor (Grieve et al., 1977; Shoemaker, 1963). The volume of the breccia lens is roughly one-half of the volume of the crater itself (Grieve and Garvin, 1984; Settle, 1980).

Complex craters possess a more complicated structure than simple craters (for a recent review, see Kenkmann et al., 2013). On the Earth, they exhibit central structural uplifts, rim synclines, and outer concentric zones of mainly normal faulting. Images from spacecrafts show extraterrestrial craters with single or multiple central peaks, flat inner floors, and terraced rims (**Figure 1**). The depths of complex craters increase with increasing diameter but much more slowly than the depths of simple craters (Pike, 1977a,b).

The transition between simple and complex craters occurs over a relatively narrow diameter range on all solar system bodies and seems to scale as the inverse power of the surface gravity (e.g., Hartmann, 1972). Thus, the simple–complex transition (Pike, 1980) is relatively well determined on the Moon at about 15 km in diameter. On Mercury and Mars, it is about 11 and 7 km in diameter, correspondingly, and 2–4 km in diameter on Earth (depending on whether the crater forms in sedimentary or crystalline rocks). On icy satellites, the transition depends on the low-temperature ice strength and the presence or absence of a sub-ice liquid mantle (Moore et al., 2001; Schenk, 2002; Schenk and Ridolfi, 2002; Schenk et al., 2004). Hartmann and Wood (1971) described a broadening of central peaks into ring of peaks, for which they coined the term *peak ring*. Peak rings possibly mark a transition to fully configured multiring basins.

Impact basins are the largest impact structures. On some bodies, they exhibit many rings, being named as multiring basins. The classic basin example is Orientale on the Moon's western limb (eastern limb in terms of sky coordinates used by early telescopic observers). First recognized on rectified lunar photographs in 1962 (Hartmann and Kuiper, 1962), multiring basins appear to form as a tectonic response of the lithosphere to the crater created by the impact (McKinnon and Melosh, 1980; Melosh and McKinnon, 1978). A review of morphology and occurrence of basins is published by Spudis (1993). The data from recent space planetary missions resulted in the enlarged volume of data about basins and their deep structure on the Moon (Crosby and McKenzie, 2005; Fassett et al., 2012a; Pieters et al., 1997; Potts and von Frese, 2003a,b; Sugano and Heki, 2004; Wieczorek and Phillips, 1999) and Mars (Hiesinger and Head, 2002; Neumann et al., 2004; Potts et al., 2004; Zuber et al., 2000). New data about Mercury have also been published (Andre and Watters, 2006; Andre et al., 2005; Baker and Head, 2013; Fassett et al., 2012b).

10.10.4 Basics of Impact Cratering Processes

Craters form in various shapes and under different conditions on each of the solid planetary bodies in the solar system. If the cratering process is well enough understood, craters make up a unique sensing system for understanding the evolution of the solar system. With a good set of crater scaling laws, relating crater and projectile SFDs, the role of the underlying geology can be derived. The key parameters are not only the projectile size and velocity but also material properties. Theoretical solutions make use of the analogy between nuclear explosions and impact crater formation in their initial phases by a point source approximation (review by Holsapple, 1993). Thus, it allows scaling the cratering process by power-law forms and the impact energy relates through a coupling parameter to the *transient* crater cavity size. The later modification stages are crater size-dependent and need to be considered separately to define the final crater size. Instructive introductory reviews were recently published by Melosh (2013) and Collins et al. (2013).

10.10.4.1 Principal Stages of Impact Crater Formation

The association of high-pressure phases of quartz, coesite and stishovite, is a reliable mineralogical criterion for an impact crater origin. It also suggests that the impact process as a whole can be described in analogy to an explosion, in which the initial kinetic energy of the projectile does work on the target to create a visible depression (the crater), to shock-metamorphose the target material, and to heat both projectile and target. The sequence of events in a high-velocity impact may be presented as a set of several sequential stages. Each of these stages is dominated by a specific set of principal physical and mechanical processes. It is convention to distinguish three main stages of an impact event (Gault et al., 1968; Melosh, 1989). These stages are (1) contact and shock compression, (2) transient crater cavity growth by crater material ejection, and, finally, (3) transient crater cavity modification (slumping or collapse). These stages are not strictly separated, but are used for convenience in the analysis of the impact process because they highlight the dominant mechanisms.

During the first stage of *contact and shock compression*, the energy released by the deceleration of the projectile results in the formation and propagation of shock waves away from the point of impact. Peak shock pressure is of the order of the stagnation pressure ρU^2, where ρ is the smaller of either the projectile or target density and U is the impactor velocity. At velocities above a few km s^{-1}, the pressure greatly exceeds the strengths of rocks (a few GPa at high pressure) and the process can be treated hydrodynamically. Shock waves propagate out of the point of impact, decay, transform to stress waves and, at larger distances, to the elastic (or seismic) waves.

After release from high shock pressure, accelerated target material moves out of the impact point, and *excavation and opening the transient crater cavity of a growing impact crater* follows. Studies of the crustal thickness beneath large lunar basins support the hypothesis of *proportional scaling* for the dimensions of the transient crater cavity up to craters at least 500 km in diameter (Wieczorek and Phillips, 1999). In many numerical model simulations, the floor of the *transient* crater achieves its maximum depth and begins to rise into a central peak while the diameter is still increasing (Melosh, 1989). The extent of the subsequent modification of the transient crater cavity depends on the size of the crater. The hiatus between the point in time when the maximum crater depth is reached and the point in time when the radial excavation flow has ceased is more pronounced the larger the crater and the more important the effect of gravity. In small craters, for example, at laboratory scale at which most scaling laws were derived, the definition of the transient crater is trivial as it is the final crater dimension.

Details of the *transient crater cavity modification* by wall slumping for simple craters are presented by Grieve and Garvin (1984). A full-scale review of the mechanics of the transient crater cavity collapse in the case of complex crater formation is given by Melosh and Ivanov (1999). The general overview of complex crater formation presented by Melosh (1989) is still the best introduction. Some particular issues are updated in more recent papers about numerical modeling of impact craters (Collins et al., 2002, 2008; Ivanov, 2005; Morgan et al., 2000; O'Keefe and Ahrens, 1993, 1999; O'Keefe et al., 2001; Senft and Stewart, 2008).

10.10.4.2 Impact Crater Scaling Laws

Scaling laws relevant to impact cratering describe a set of rules, both experimentally derived and theoretically assumed, and formulated to establish relationships between properties and parameters of an impactor (projectile), the planetary surface (target), and the resulting impact crater under conditions of different planetary bodies, such as gravity and specific material properties. Originally, scaling laws were formulated to make a theoretical interpolation of laboratory experimental data, mostly for metal targets (Kinslow, 1970), and to extrapolate the results of impact experiments at velocities achieved at laboratory-scale to a natural impact velocity range. Later, the focus changed to rock and soil targets when planetary scientists tried to estimate the size of projectiles that created craters on planetary bodies. These efforts on rock and soil targets and explosion cratering studies were collected by Roddy et al. (1977). While for metal targets, the shear strength of metals dominantly limits the size of the growing transient cavity, for natural planetary targets, where crater diameter ranges from less than millimeters to more than 1000 km, one observes a transition from strength-dominated formation of small craters to gravity-dominated formation of large craters. *Large* and *small* crater diameters depend on the intrinsic target strength, which adjusts in a complicated way during the cratering process. This adjustment is influenced by the brittle damage of the intact rocks, additional fragmentation of real fractured rocks, mechanical dispersion of shock energy in sands and regoliths, temporary decrease of friction, and thermal softening, when the rock strength vanishes near to the melting point. For this reason, it is convenient to refer to *effective* rock strength, usually implemented as one parameter in the available theoretical models. However, this parameter, in reality, is highly variable in time and space during the cratering process.

Several approaches to scale cratering effects for a variety of impact velocities, target strength parameters, and an impact angle exist. They are used to scale crater size observed on different planets to find the crater-forming projectile size, which is then used to compare the similarities and differences of cratering rates. The reliability of this comparison defines the accuracy of interplanetary crater-retention age recalculations. Scaling relations seek to find analytic descriptions, which relate input parameters at ranges that can cover several orders of magnitudes and the dimensions of the final parameter without the simulation of the entire physical process. Early theoretical studies on self-similar solutions of the second kind (Zeldovich, 1956) have resulted in a concept, later named 'the late-stage equivalence' (Dienes and Walsh, 1970): The impact cratering process at distances much larger than the projectile size is similar for all impacts in the same target, if the value of the so-called coupling parameter (some combination of the mass and velocity of the projectile) is constant. There exist several approaches of scaling impact crater formation.

10.10.4.2.1 The concept of coupling

The central point of the coupling-parameter concept is that the cratering efficiency of one impact will be the same for all projectiles with the same coupling-parameter value. Because the details of the energy release at the source point do not affect the later process significantly, Dienes and Walsh (1970) had proposed a coupling parameter to scale the shock pressure decay under the point of impact in the form of a characteristic length scale, L, for a given impactor and, thus, a measure for the penetration depth:

$$L = D_p(\delta/\rho)^{\nu}(U/c_b)^{\mu} \qquad [1]$$

where D_p is the projectile diameter, δ/ρ is the projectile-to-target density ratio, U is the impact velocity, and c_b is the bulk velocity of the target material, defined as $c_b = (K/\rho)^{0.5}$, where K is the bulk compression modulus. ν and μ are dimensionless exponents, which are derived from experiments. For the density-ratio exponent, the value of $\nu = 1/3$ gives a good approximation for available data. The velocity exponent μ is bounded by theoretical extreme values for the velocity exponent related either to a maximum when scaled by the energy ($\mu = 2/3$) or to a minimum when scaled by the momentum ($\mu = 1/3$) of the impactor. For the same projectile density, a simple *energy scaling* demands that the value $D_p U^{2/3} = \text{const.}$, while experiments and numerical modeling reveal an *equivalence of mechanical action* (e.g., the same crater dimensions) for projectiles with $D_p U^{\mu} = \text{const.}$ only for velocity exponents $\mu < 2/3$, for example, $\mu \approx 0.55$–0.58 for competent nonporous targets and $\mu \sim 0.45$ for porous targets like dry sand. The fundamental reason for the inequality $\mu < 2/3$ is that at higher impact velocity, a small amount of material near the impact point is overheated and ejected, and that decreases the amount of energy available for the crater formation at later stages. The lower theoretical limit resulting from *momentum scaling* demands that $\mu > 1/3$ (Holsapple, 1993; Holsapple and

Schmidt, 1982). The transition between strength- and gravity-dominated regimes depending on projectile size is not yet considered. The transition is gradual and becomes important in the late stage of the transient crater cavity growth.

The scaling of transient crater cavity depth, z, below the impact point with the length scale L allows us to present the shock pressure, P, decay in the form

$$P/\rho c_b^2 = f_p(z/L) \quad [2]$$

where f_p is the universal function for a wide range of impact conditions. Experimental data for metal targets are given by Dienes and Walsh (1970). Progress in numerical modeling techniques promoted the investigation of shock pressure decay in *geomaterials* such as rocks. Almost all rock components typical for planetary crusts pass through a solid–solid phase transition under compression (quartz–coesite–stishovite transition is a typical example) and make the scaling of impact cratering in rock more complicated than for metal targets. However, available numerically modeled data show reasonably good convergence to a general shock pressure decay function, as given in dimensionless form of eqn [1]. For target material with a simple equation of state, Ivanov (1981) showed that the shock pressure decay may be expressed as

$$P/\rho c_b^2 = (3 \pm 1)(z/L)^{-2.5} \quad [3]$$

with the best choice of $\mu = 0.58$ recommended by Dienes and Walsh (1970). Pressure decay with distance from the impact point in geomaterials may happen on a shorter length scale than, for example, in metals, because the solid–solid phase transition and initial porosity require additional energy, which dissipates by additional residual heating of the shocked material.

A short note should be added about the widely cited concept of a so-called isobaric core. Numerical modeling by Pierazzo and Melosh (1999) revealed that the geometry of shock pressure isobars may be represented by a truncated sphere below the point of impact. In the limits of a certain isobar near the projectile contact point, the maximum pressure is almost constant and close to the initial contact pressure. This zone is cited as an 'isobaric core.' The reader should be aware that inside the 'isobaric core,' the shock pressure is about the same, indeed, but the contours of equal shock pressures do not coincide with the surface of the shock wave – the same shock pressure inside the 'isobaric core' is reached at various instants of time close to the centerline and far from it. The effect is clearly shown by Melosh (2013) and Figure 3.1 therein. The instant shock front surface is much closer to a hemisphere with the center in the contact point than a truncated spherical surface.

Holsapple and Schmidt (1980), Holsapple and Schmidt (1982), Holsapple and Schmidt (1987), and Schmidt and Housen (1987) had found a set of parameters to scale cratering dimensions, not explicitly considering target material compressibility yet. The coupling (parameter) of impact energy or momentum into the target depends on the specific target (rock) properties (e.g., solid–solid phase transitions, porosity, and effective strength). Thus, for example, in numerical models, it stays challenging to incorporate the momentum or energy transfer correctly, producing the appropriate shock-wave propagation. The shape of the shock front depends on the sets of coupling parameters, but it has been proven to be useful in many applications of *high-velocity* impacts when the impact velocity is larger than the sound velocity of the target and the projectile is not infinitely strong. For *low-velocity* impacts, which are subsonic relative to the target material (sound velocity), and/or for deeply penetrated projectile, the coupling-parameter function may be different, particularly if it depends on impact velocity not as an exponential function. For example, low-velocity impacts in sand are well described with a coupling-parameter proportional to a linear combination of U and U^2 terms (Mizutani et al., 1983). In the succeeding text, we concentrate on high-velocity impacts.

10.10.4.2.2 Strength and gravity scaling

For fixed values of the coupling parameter, the kinetic energy of the excavation flow accounts for either mostly plastic work against the strength of target material (*strength regime*) or mostly potential energy of the growing cavity in the gravity field (*gravity regime*). In the former case, the energy consumed during the transient cavity growth to a characteristic size a (the linear scale may be described by crater depth, radius, or the cube root of the volume, $V^{1/3}$) is proportional to Ya^3 (the multiplication of a transient crater volume, proportional to a^3 by the effective strength Y), while in the latter case, the consumed energy is proportional to $\rho g a^4$ (the multiplication of the mass extruded from the transient cavity, proportional to ρa^3, by the gravity acceleration, g, and the effective height of the mass uplift, proportional to a). Craters formed in the gravity regime need increasingly more energy to make a larger crater. These large craters are relatively small with respect to their projectile and shock melt-zone size. This implies that the largest impact basins on terrestrial planets may have transient cavities only a few times larger than the projectile size and the exact proportions depend on the assumed impact velocity. In the intermediate-sized crater range, both gravity and strength energy consumption mechanisms operate simultaneously.

There are many ways to express the transition from strength-to-gravity regimes. The basic experimentally derived scaling laws (Schmidt and Housen, 1987) use the π-theorem (Buckingham, 1914). For the case of crater scaling, the π-scaling is described in detail by Melosh (1989) (for a review, see Holsapple, 1993):

$$\pi_D = K\pi_2^{-\alpha} \quad [4]$$

where π_D is the scaled transient crater diameter D_a,

$$\pi_D = D_a(\rho/m)^{1/3} \quad [5]$$

The gravity-scaled projectile size (for a sphere of a diameter D_p equivalent mass) in the gravity-dominated regime is given by

$$\pi_2 = (1.61 g D_p)/U^2 \quad [6]$$

and in the strength-dominated regime, it is

$$\pi_2 = Y[\rho U^2] \quad [7]$$

where Y is an effective strength of the target material, keeping in mind that this property is highly variable during the cratering process in space and time. The use of a single value can only refer to the averaged value.

Here, D_a is the transient apparent crater diameter, ρ is the target density, m is the projectile mass, U is the impact velocity, g is the gravitational acceleration, and D_p is the projectile diameter. Schmidt and Housen (1987) determined coefficients in eqn [4] for various materials from experimental data, with coefficients for some typical rock types such as for porous (e.g., dry sand) targets $K=1.68$ and $\alpha=0.17$ and for nonporous rocks $K=1.6$ and $\alpha=0.22$. The parameters for nonporous rocks can be experimentally determined only for the strength regime, and the values given here are not necessarily applicable for the gravity regime scaling.

The elaboration of the hydrocode-friendly model of porosity (Wünnemann et al., 2006) and the extensive modeling of vertical and oblique impacts (see succeeding text) resulted in the appropriate change of terminology. What we previously named *nonporous* scaling law is more appropriate to name "*nonporous, zero friction* scaling law. Note that Schmidt and Housen (1987) calibrated this law by experiments in water-saturated sand (the filling of pores with water sufficiently decreases friction). The formerly *porous* scaling law calibrated by dry sand experiments appears to have its different exponent in eqn [4] mostly due to dry friction. It is more appropriate to name it *dry friction* scaling law (porosity decreases the coupling efficiency but keeps the α value close to 0.17 for a wide range of porosities – at least in the available numerical models; Nowka et al., 2010; Wünnemann et al., 2011, 2012).

Figure 2(a) and **2(b)** illustrates the scaling for dry and wet sand (*dry friction* and *nonporous, zero friction*) rocks for comparison and the experimental data used to define scaling constants. Porous rocks, dry sand, and lunar regolith experimental data are shown in comparison. The scaling law represents the data well (**Figure 2(a)**). Nonporous rock scaling laws are compared to wet sand data. Schmidt and Housen (1987) observed a mismatch between their experimental crater size values for wet sand targets and an exponential extrapolation for the pure gravity scaling, because the experiments covered the strength–gravity transition region. The experimental laboratory data can be expanded by numerical modeling results, in which both the *transient* crater cavity diameter (all scaling laws refer to the transient crater cavity only) and the *final* rim diameter have been recorded. In **Figure 2(b)**, numerical results for terrestrial craters with rim diameters from ~5 to ~200 km in layered targets (sediments over granitic crust over dunitic mantle) form a natural continuation of the high-G experimental data for wet sand, but with a shallower slope (closer to a slope for porous targets) in π_D–π_2 coordinates. (In centrifuge experiments, G is the artificial gravity value normalized as the ratio of the centripetal acceleration to the normal terrestrial free fall gravity acceleration $g=9.81\ \mathrm{ms}^{-2}$. These experiments make use of the proportionality between gravitational acceleration and projectile energy, so that impact experiments in a centrifuge can extend the transient crater cavity range to larger diameters when normal terrestrial free fall gravity acceleration is considered.) The reason for this behavior may be the presence of dry friction in numerical models, not well discussed in early nonporous scaling law derivation (Schmidt and Housen, 1987). Both experimental (Schmidt, 1980) and numerical modeling (Wünnemann et al., 2006) data show that porosity and dry friction in targets should be decoupled in an updated version of scaling technique now under construction.

The first steps toward updated scaling laws have been done recently (Elbeshausen et al., 2009; Nowka et al., 2010; Wünnemann et al., 2011, 2012). These authors published a series of numerical models where the transient crater dimensions were systematically calculated for various values of the dry friction coefficient and porosity of the target material (**Figure 2(c)** and **2(d)**). Most recent experimental work on porous, wet, and dry sandstone suggests a complex relation of porosity and pore space saturation to influence the cratering process, thus a challenge to estimate the relation between the transient crater cavity and final crater diameter. In the strength regime, a coincidence of these two measures is assumed (Poelchau et al., 2013).

The π-theorem relations may be rewritten in the following familiar form, for nonporous, zero friction rocks:

$$D_{tc} = 1.16\,(\delta/\rho)^{1/3} D_p^{0.78} (U)^{0.44} g^{-0.22} \quad [8]$$

and for dry friction (dry sand) material:

$$D_{tc} = 1.25\,(\delta/\rho)^{1/3} D_p^{0.83} (U)^{0.34} g^{-0.17} \quad [9]$$

Relations presented earlier in the text are valid for the gravity regime of cratering. The procedure of how to approximately include the strength–gravity transition, inspired by Holsapple and Schmidt (1979), is described in Neukum and Ivanov (1994) and Ivanov et al. (2001). Arithmetically, the engineering equation for nonporous, zero friction rocks is transformed to

$$\left(D_{tc}/D_p\right)^{0.78} = 1.16(\delta/\rho)^{1/3} (U)^{0.44} (gD_{tc})^{-0.22} \quad [10]$$

and consequently to

$$D_{tc}/D_p = \left[1.16(\delta/\rho)^{1/3} (U)^{0.44} (gD^{tc})^{-0.22}\right]^{1/0.78} \quad [11]$$

Finally, all numerical values for δ, ρ, U, are combined into one coefficient C_D,

$$D_{tc}/D_p = C_D/(gD_{tc})^{0.282} \quad [12a]$$

and, correspondingly, for 'dry sand' (dry friction) scaling (eqn [9])

$$D_{tc}/D_p = C_D/(gD_{tc})^{0.205} \quad [12b]$$

In the strength regime, the ratio of D_{tc}/D_p is a constant. To make a smooth transition from the strength-to-gravity regime, we assume that

$$D_{tc}/D_p = C_D/\left[g\left(D_{sg} + D_{tc}\right)\right]^{0.282}$$
for nonporous, zero friction rocks, and [13a]

$$D_{tc}/D_p = C_D/\left[g\left(D_{sg} + D_{tc}\right)\right]^{0.205}$$
for dry friction (dry sand) material [13b]

where D_{sg} is the effective boundary between gravity- and strength-dominated regimes of crater formation. For the discussion on the actual D_{sg} value for terrestrial rocks, see Holsapple and Schmidt (1979), Croft (1981), and Neukum and Ivanov (1994).

Here, we have a smooth approximation of the transition to strength craters for small craters $D_{sg} \ll D_{tc}$, and the D_{tc}/D_p ratio is constant for a given C_D value:

$$D_{tc}/D_p = C_D/\left[gD_{sg}\right]^{0.282}$$
for nonporous, zero friction rocks, and [14a]

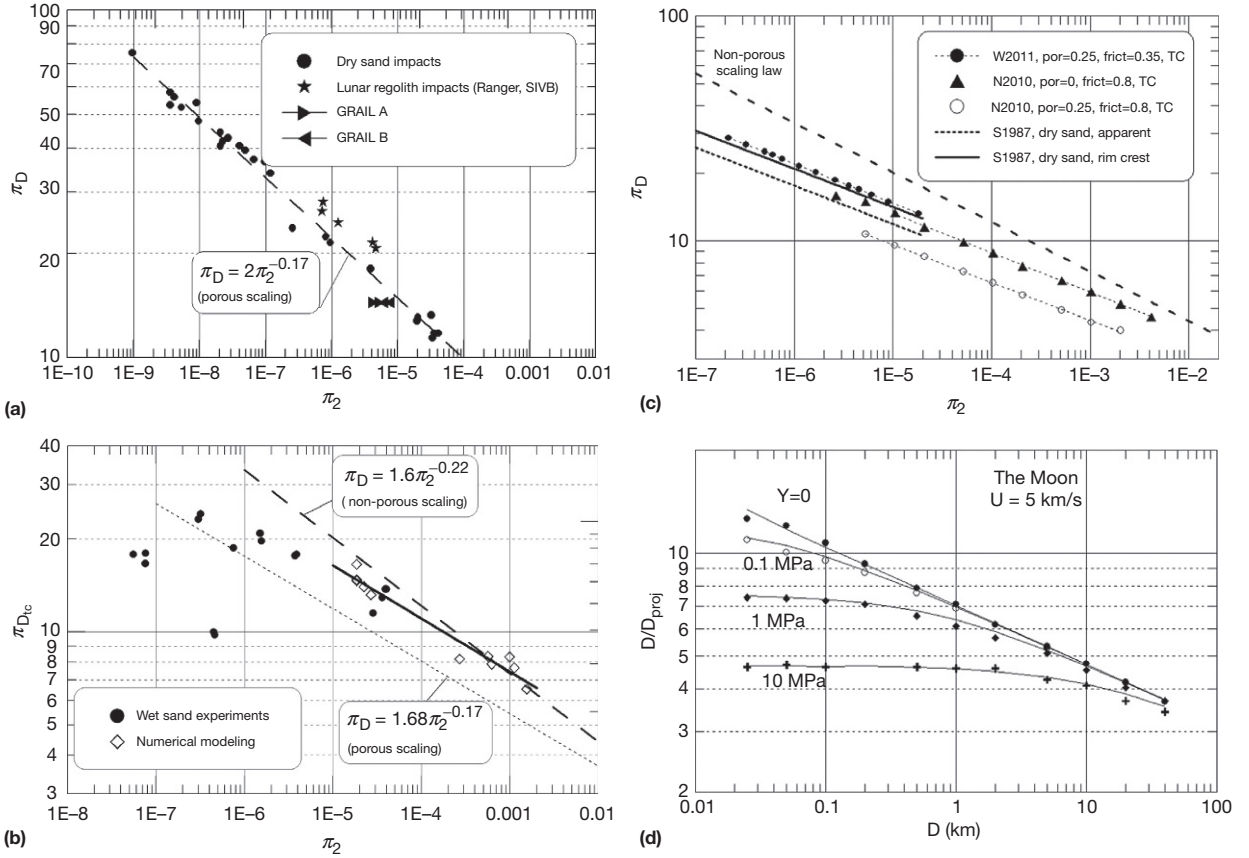

Figure 2 (a) π-Scaling for dry sand ('porous dry friction rock') for the rim crater diameter. Laboratory experimental points (Housen and Holsapple, 2003; Schmidt, 1987) are compared with artificial lunar craters created by Ranger SIVB, and GRAIL spacecraft impacts (Moore, 1972; Witaker, 1972).(Lunar crater diameters are measured on recent LRO image data (http://lroc.sese.asu.edu). GRAIL craters are formed at a steep slope of ~25° at small velocities of 1.6 km s^{-1}. The crater and topographic data are provided at http://lroc.sese.asu.edu/news/index.php?/archives/719-Impact!.html. For the assumed crater diameter of 6 m, the uncertainty in the average projectile density in the range from 130 to 260 kg m^{-3} is shown. Being smallest of all artificial impact craters, GRAIL craters may manifest the influence of the regolith cohesion, resulting in downshifted position of π_{Dtc} values.) (b) Scaled transient crater radius π_{Dtc} versus scaled projectile size, π_2, from experimental Boeing Lab data (Schmidt and Housen, 1987) for wet sand (black circles), and from numerical modeling (Ivanov, 2005; Ivanov and Stoffler, 2005; Joeleht et al., 2005; Stöffler et al., 2004) as open diamonds, transient cavity is defined as in (Wünnemann et al., 2006). Numerical modeling data appear as a natural continuation of experimental data, following however an exponent of −0.17, similar to experimental exponent found for dry sand, but not as steep as the assumed 'nonporous' value of −0.22 (Schmidt and Housen, 1987). It is unclear whether finite friction in the numerical model is the cause for this observation. (c) Numerical modeling results for porous targets with dry friction in comparison with experimental data for dry sand (Schmidt, 1987; solid black line is for rim crest diameter, dashed line is for the apparent diameter; S1987 in the legend). Black circles are model data for the transient cavity from Wünnemann et al., 2011, for 25% porosity and friction coefficient of 0.35. Triangles (zero porosity) and open circles (25% porosity) are for scaled transient cavity diameters in a material with friction coefficient of 0.8 (Nowka et al., 2010). Upper dashed line is for the 'nonporous, zero friction' scaling law (scaled eqn [4] and dimensional eqn [10]). (d) Numerical models for transient cavity dimensions in a nonporous material with various strengths (cohesion) published by Nowka et al. (2010) in dimensional coordinates (lunar gravity, impact velocity of 5 km s^{-1}).

$$D_{tc}/D_p = C_D/[gD_{sg}]^{0.205}$$

for dry friction (dry sand) material [14b]

The values of $1/[gD_{sg}]^{0.282}$ and $1/[gD_{sg}]^{0.205}$ represent the effective target strength parameter, so that the smaller the strength, the larger the crater and the smaller the transitional diameter between craters formed in strength and gravity regimes.

Preliminary (transient cavity only) modeling by Nowka et al. (2010) and Wünnemann et al. (2011) illustrates how target porosity decreases the crater efficiency of an impact (**Figure 2(c)**). For example, porosity of 25 vol% decreases the π_D value by a factor of 1.6 (with a proper account for smaller density of the porous material). One more effect to study in the near future is the thermal softening of geomaterials with the dry friction. Heating of materials due to the shock compression/decompression heating and the plastic work may decrease the friction coefficient. It results in the gradual change from the 'dry friction' scaling law (eqn [14b]) to the 'no friction–gravity-dominated' scaling law (eqn [14a]). Preliminary modeling (Ivanov and Kamyshenkov, 2012) illustrates the transition. Previously, the idea of the thermal softening was proposed for the yield strength (cohesion) decrease only (O'Keefe and Ahrens, 1993, 1999).

Figure 2(d) illustrates the strength–gravity transition in the model target material with zero porosity, constant friction coefficient, and variable strength (cohesion) computed by Nowka et al. (2010). Theoretical curves are fitted to individual model data with eqn [13b]. The comparison of the cohesion value, Y, in the iSALE code and the characteristic strength/gravity transition diameter D_{sg} gives an approximate rule for the lunar gravity: $D_{sg}(\text{m}) \cong 5\,Y(\text{kPa})$. Note that 1 bar cohesion is equivalent to 100 kPa.

More studies of nonuniform targets (e.g., where porosity decreases with depth) are needed to model impact craters on asteroids (8–10% of a bulk porosity of Vesta; Toplis et al., 2013) and the Moon (Wieczorek et al., 2013), where porosity is proven to exist in the whole crust and upper mantle. Some preliminary models of a nonuniform Moon are published by Wünnemann et al. (2012).

The transient crater cavity diameter is proportional to the rim crater diameter as $D \approx (1.25 \pm 0.05) D_{tc}$ for simple craters, and, according to Croft's model (Croft, 1985),

$$D_{tc} = D_{sc}^{0.15} D^{0.85} \qquad [15a]$$

or, vice versa,

$$D = D_{sc}^{-0.18} D_{tc}^{1.18} \qquad [15b]$$

for $D > D_{sc}$, where D_{sc} is the simple-to-complex crater transition diameter. One should note that the simple-to-complex transition is poorly investigated and the recipe mentioned earlier in the text is the simplest but an internally consistent one. Equations [15a] and [15b] were obtained from the geologic reconstruction of partially eroded terrestrial craters. Numerical modeling gives an opportunity to get similar relations directly by the comparison of transient cavity diameter and the final rim diameter of a collapsed crater (Figure 3). The exponent in eqn [15b] is close to model values (Figure 3) and proves the general validity of Croft's model. However, a final conclusion is only reached with further natural and model data reconciliation.

For other planetary bodies, the D_{sc} value may be assumed from crater morphology transition (Pike, 1980). Numerical modeling of the terrestrial impact crater formation extended to the end of target material motion (see references in the caption for Figure 2) allows a final approximation of the relationship between projectile diameters, D_p (in km); impact velocities, U (in km s^{-1}); and the final rim crater diameter, D (in km), for a vertical impact as

$$D = 4\left(D_p U^{0.58}\right)^{0.91} \qquad [16]$$

valid for the diameter range shown in Figure 3. The general behavior of the D/D_p ratio for craters in lunar nonporous rocks has been presented in Neukum and Ivanov (1994) and Ivanov et al. (2001). The general D/D_p dependence on the final crater diameter for lunar craters is shown in Figure 4, constructed with the impact velocity of 18 km s^{-1}, lunar regolith density of 1900 kg m^{-3}, and projectile and bedrock density of 2700 kg m^{-3}. Equation [16] and the scaling relation shown in Figure 4 will be used to compare SFD of projectiles and impact craters on the Earth and the Moon (see Section 10.10.6.2).

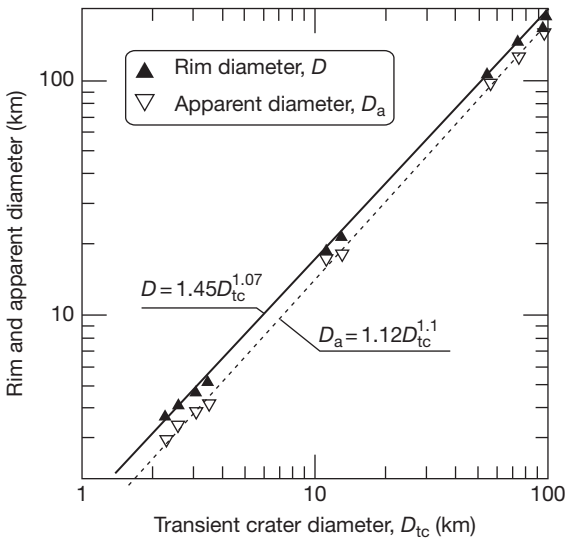

Figure 3 The relation between transient crater diameter and both rim crest and apparent final complex crater diameters from direct numerical modeling of terrestrial craters with diameters from ~4 to ~200 km (see references in Figure 2(b)).

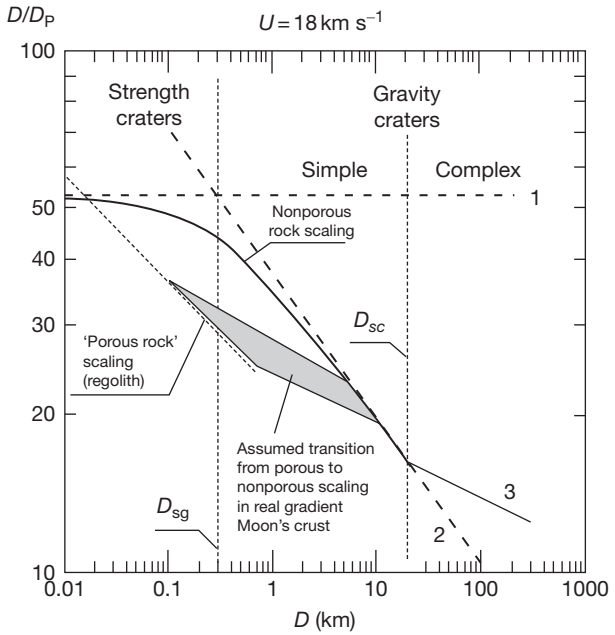

Figure 4 An example of the lunar crater scaling. The upper layer of the Moon is constructed of porous regolith, and for an assumed impact velocity of 18 km s^{-1}, the crater/projectile diameter ratio is of the same value as for the strength scaling for craters in nonporous bedrocks. For craters in nonporous bedrocks, the D/D_p ratio gently declines from strength scaling (D/D_p = const., dashed line 1) toward the gravity scaling (dashed line 2), but at $D \sim 15$ km, craters undergo widening due to the gravity collapse. For realistically layered lunar crust with a gradual transition for a relatively porous megaregolith to the solid rocks, one may assume a gradual transition from the porous to nonporous scaling for D between ~0.5 and ~10 km. Future studies of cratering in variably porous lunar crust should clarify the presented qualitative scheme.

10.10.4.2.3 Scaling of the impact angle

Vertical impacts of celestial bodies into planetary surfaces are suitable for computational and experimental studies. However, both vertical and grazing impacts have a very low probability to occur. It was shown for nongravitating spherical bodies (Gilbert, 1893) and for spherical planets with their natural gravitational attraction (Shoemaker, 1962) that the probability of impacts of a random flux of projectiles from infinity at various angles has a domical-shaped angle distribution with a maximum at 45°:

$$f_\phi = 2\sin\phi\cos\phi\,\mathrm{d}\phi \qquad [17]$$

where f_ϕ is the probability of impact in the interval of angles from ϕ to $\phi+\mathrm{d}\phi$. The convention is to measure the angle of impact from the horizon is $\phi=0°$ for grazing impacts and $\phi=90°$ for vertical impacts. Equation [17] is considered valid for planets and projectiles revolving around the Sun, where they form circular craters under most impact angles. Depending on the target properties and its *effective* strength, the crater becomes more elongated for impact angles below about 15° (Gault and Wedekind, 1978). This critical angle can vary depending on the crater efficiency (Collins et al., 2011; Elbeshausen et al., 2013). An oblique impact is less efficient than a vertical impact. Experimental modeling reveals, for example, that for the same projectile and the same impact velocity, the crater volume, V, decreases approximately as

$$V(\phi) = V(90°)\sin^\gamma\phi \qquad [18]$$

where $V(90°)$ is the crater volume for vertical impacts and the exponent γ is in the range from 1 to 2 depending on the target properties. Gault and Wedekind (1978) proposed γ between 1 and 2 for impacts in monolithic granite blocks and projectiles of aluminum, representing the strength regime, and $\gamma=1$ for impact in porous targets prepared of noncohesive dry sand and volcanic adhesive pumice, which is analog to the gravity regime. These results are widely cited despite the obvious difference in impact conditions: At a maximum impact velocity, v, of 7 km s^{-1}, impacts into sand and pumice are supersonic with v four to five times larger than the sonic speed in the target material, while for solid rocks, it occurs in subsonic to sonic regime, because the velocity v of 5–7 km s^{-1} is close to the longitudinal elastic wave velocity of solid rock. Pierazzo and Melosh (2000b) tested numerically the assumption that the experimental results of Gault and Wedekind (1978) can be approximated by assuming that the value of the velocity U in scaling laws for vertical impacts for an oblique impact may be replaced with $U\sin\phi$, representing the vertical component of a projectile velocity (Pierazzo and Melosh, 1999, 2000a,b). However, the real nature of oblique impact looks more complicated. The repetition of such experiments for monolithic rocks (Burchell and Whitehorn, 2003) confirms the validity of $\gamma=1$ similar to the porous target value obtained by Gault and Wedekind (1978). Preliminary last-stage numerical modeling (Artemieva and Ivanov, 2001; Ivanov and Artemieva, 2001, 2002) revealed that for a velocity of 20 km s^{-1}, the efficiency of oblique impacts decreases with $\sin\phi$. This is an observation that indicates a decrease less dramatically than suggested by the vertical velocity component paradigm. The issue deserves further investigation. As a tentative recipe, one can take into account that the 45° and steeper high-velocity impact (15 km s^{-1} and faster) may be as effective as the vertical impact. For low-velocity impacts (5–6 km s^{-1}), preliminary 2-D numerical tests show that it is best approximated with $\gamma=1.6$ for strong ductile target materials (Davison et al., 2011), while for target materials with no or little cohesion, it is not the case (Elbeshausen et al., 2009).

10.10.4.2.4 Impact heating, melting, and vaporization

The essential part of the initial projectile kinetic energy transforms into target material thermal energy, distributed around the crater. The heating is the result of energy conversion of the residual internal energy after the shock compression and decompression cycle and depends on the shock-wave amplitude. The further from the point of impact, the smaller impact heating.

Close to the point of impact, the zone of the originating impact crater cavity, heat large enough to change the thermodynamic state of the target material above its boiling point is deposited by the irreversible (unisentropic) process of shock-wave compression. However, for typical impact velocity of 20 km s^{-1} and for typical terrestrial planet crustal rocks, such as granite, basalt, and anorthosite, impact heating is not strong enough to fully vaporize the rocks. Most probably, a state of partial vaporization is reached, where rock melt at liquidus temperature (pressure-dependent) is in equilibrium with gaseous phases. The detailed thermodynamic history for different target materials can be calculated using *equation of states*. During partial vapor cooling, the chemical content of liquid and vapor phases can vary with a possible quenching at about 2000°K. In experiments, a difference in condensation products is observed under cooling and expansion after the shock-induced nonequilibrium process, when compared to quasi-equilibrium processes. Laboratory data about simulated rock vaporization are illustrated by Gerasimov et al. (1999). The presence of various oxides with temperature-dependent chemistry, for example, can be used to constrain the models (e.g., Yakovlev and Basilevsky, 1994).

For residual temperatures below the boiling point, shock heating results in *impact melting* of rocks. In terrestrial craters, impact rocks are easily identified by texture. The important differences of impact melt in comparison with volcanic melts are (1) the presence of large volumes of material melted above the solidus temperature (overheated melt) and (2) the presence of heavy fragment loading, untypical for volcanic melts. The history of fragments (clasts) incorporated in the impact melt may be very complicated – fine dust may be digested by melt, while large boulders seem to hover inside the quickly solidified melt body. The classification of impact-related metamorphism and rock types is still not fully settled, but some schemes and glossaries exist (e.g., Stöffler and Grieve, 2007).

With the exception of very large craters with diameters of about 200 km and larger, impact melt solidification has a two-stage cooling history (Onorato et al., 1978). During the first stage of cooling, the local thermal equilibrium with incorporated clasts is achieved. Later, the equilibration (cooling) of the entire melt body occurs by convection (in large craters) and heat conduction (in smaller craters), where local thermal equilibrium results in

temperatures close to solidus and correspondingly large viscosity. In terrestrial craters with diameters below 100 km, such as Manicouagan, clast cooling decreases the impact melt temperature to solidus in about 100 s. On Venus, the local thermal equilibrium is reached slower due to the smaller thermal gradient between clasts and melt and increases the final melt temperature, because Venus has a larger crust temperature (~740 K) than Earth. Hence, on Venus, impact melt is mobile an order of magnitude longer time (Ivanov et al., 1992). In large impact craters on Earth, such as Sudbury, the volume of impact melt is so large that thermal equilibrium is already reached at temperatures above the solidus and even above the liquidus, so that magmatic processes in the melt body, including convection, can continue (Zieg and Marsh, 2005).

Experimentally, the vaporization or melt volume has not been determined, because velocities under laboratory conditions are not yet high enough. Instead, impact melt volumes of a few terrestrial impact craters have been estimated (Cintala and Grieve, 1998a,b; Grieve and Cintala, 1992) and were compared with theoretical values obtained from shock-wave propagation and crater scaling laws. Today, this is the only method available to verify scaling laws for large impact craters. Typically, the melt volume or mass is given relative to the projectile volume or mass. A comparison made by several authors gives the estimated accuracy of a factor of 2 for the projectile mass and a factor of $2^{1/3}$ for the projectile size, respectively, for assumed projectile density, impact angle, and velocity (Ivanov, 1981; Pierazzo et al., 1997; Ugalde et al., 2005). **Figure 5** illustrates the comparison between impact melt volumes observed and estimates from scaling laws for terrestrial impact craters in a wide range of crater sizes. In the presence of porous target rocks (e.g., sandstone), the melt volume may be larger than in a nonporous rock (Wünnemann et al., 2008).

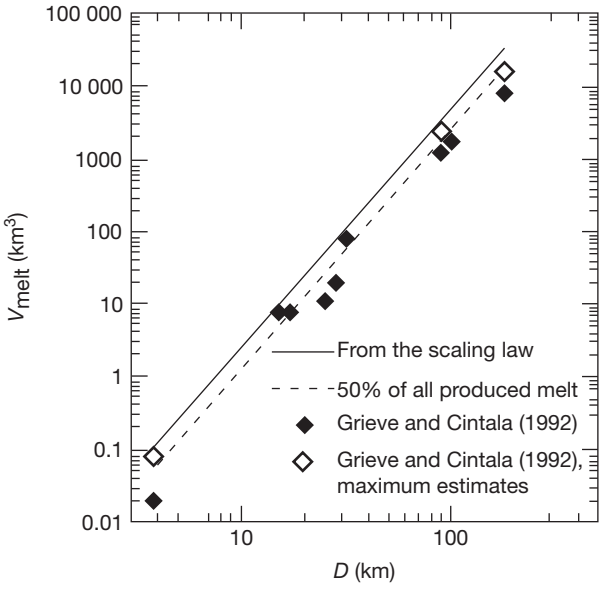

Figure 5 Comparison of estimates made using scaling laws (solid and dashed lines, constructed using data by Ivanov (1981) and Pierazzo et al. (1997)) and using geologic mapping of terrestrial impact craters, summarized by Grieve and Cintala (1992).

In summary, scaling laws are valuable rules to describe the morphometry and volume properties of impact structures with respect to the projectile. However, many details are still unexplored and often rely on either experimental or numerical approaches, and only the very small crater diameter range is covered by both. For the gravity-dominated regime, scaling laws can be highly unreliable, but it is impossible to reproduce natural impact craters by experiment. On the other hand, for small craters, the effects of the projectile energy or momentum coupling to the target, porosity, and effective strength are measurable parameters, which need to be implemented in numerical codes correctly. Although there are these numbers of uncertainties, the crater scaling is useful to study cratering distributions on the surfaces of the different planetary bodies.

10.10.5 Cratering Statistics

The bombardment history of the Moon is closely related to our understanding of planetary formation and evolution of the solar system. It turned out that the Moon is an ideal test site to study the cratering records in space and time, not only because most lunar endogenic activity ended more than 3 Ga ago, gradually decaying in time (e.g., Hiesinger et al., 2000, 2003). Over the last 3 billions of years, impact cratering alone dominated the modifications of the lunar landscape. Not only the Moon but also Mercury, Mars, and many of the giant planets' satellites kept the bombardment history of the earliest evolutionary period preserved on their surfaces, which were formed shortly after the formation of the solar system, but only the Moon has been studied by space missions extensively (space mission orbital dynamics and instrumentation are discussed in **Chapters 10.22** and **10.23**, respectively).

The Moon is the only other solar system body for which samples of known sampling site have been studied in detail, such as mineralogy and isotope ages. Absolute timescales for planetary surface evolution in the inner solar system (except the Earth) can only be derived by linking the lunar cratering frequencies with isotopically dated lunar samples. The approach of dating planetary surfaces by crater densities (i.e., the number of craters per square kilometer) was first proposed by Öpik (1960), whereas linking crater densities with isotopic ages was pioneered by Shoemaker et al. (1962). The Apollo and Luna sampling missions provided lunar rock samples that were isotopically dated; these isotopic ages were later correlated to crater densities on the lunar surface (Baldwin, 1971; Bloch et al., 1971; Hartmann, 1970a,b; Neukum et al., 1972, 1975b; Soderblom and Boyce, 1972). This permitted dating of surface features so that the planetary evolution could be studied through geologic time. These lunar cratering chronology models have not been updated since the 1970s. The most recent orbital evolution models (Bottke et al., 2012; Morbidelli et al., 2012b) compare these cratering-rate estimates for the Moon (i.e., Neukum et al., 1975a) to calibrate modeled flux evolution. However, one of the major criticisms is that these old cratering-rate estimates predict contradicting sequences of basin formation ages when compared to isotope dates.

The discovery of extrasolar planets has changed ideas on the dynamical evolution of our own planetary system and has inspired to develop the orbital migration of the gaseous planets during their primordial accretion phases (originally suggested by Zharkov and Kozenko, 1990) further. Through inward and outward migration during their formation period, these giant planets destabilize the remaining planetesimals (Gomes et al., 2005; Tsiganis et al., 2005). This could explain not only (1) what was earlier called LHB of the terrestrial planets, a spike in the inner-planet bombardment rate at around 3.9 billion years ago, originally postulated for the Moon from the isotope geochemistry of returned lunar samples (Tera et al., 1974), but also (2) the unusually small size of Mars (Hansen, 2009). Commonly used cratering statistics for planetary surface-age determination assume monotonic cratering-rate decay, but this assumption has been suggested to be dynamically unjustified. Hereby, more criticism is raised against the standard crater-counting method to determine planetary surface ages.

The possible nonsmooth cratering rate consisting of 'spikes' and 'spike tail' periods is the natural assumption, and the most probable graphic expression of the cratering rate versus time is a set of 'saw teeth' (Hartmann, 1970b). Recent modeling reveals a possible timescale of a 'spike' decay after a prominent injection of asteroids into planetary orbits of the order of 150–200 My (Bottke et al., 2007) and provided a new family of asteroids, which appeared in orbits near 'transporting' resonances. For an individual crater-retention age, the assumption of a constant (or monotonically decaying) impact rate could result in an erroneous absolute crater-retention age. However, the general stratigraphic approach (the more primary craters, the older the surface) remains a good assumption in planetology.

The crater-counting method, however, is the only tool to date planetary surface evolution when samples are not available. Uncertainties in the cratering rates and the diverse crater-production function shapes used to calibrate crater density measurements, as well as the assumed flux evolution, have resulted in many unique lunar chronology models. This diversity of lunar chronologies propagates to other planets such as Mars and adds ambiguity to the interpretation of their geologic history (e.g., Werner and Tanaka, 2011). Here, we describe some of the standard characteristics of cratering chronology model assumptions and crater SFDs, and we highlight the issues and challenges of the determination of the ultimate crater-production function (a mathematical expression for the original projectile distribution).

10.10.5.1 SFD of Impact Craters

Prerequisite for the determination of the lunar cratering chronology is the determination of the original crater SFD. There are a number of well-known and long-standing difficulties for the determination of the crater-production function. These difficulties not only are partly inherent issues of the cratering process but also and more significantly are related to the interpretation of the crater record. Numerous crater-production functions exist, because the major challenge in the development of the crater-counting technique and for surface-age determination is to find large, homogeneous, and undisturbed surfaces and to determine the true crater-production function. Observed crater distributions could be diverted due to the following:

1. *Average impact velocities*, which compress or stretch the curve along the diameter axis
2. *Resurfacing processes*, which shallow the curve
3. *Admixture of secondary craters*, which steepens the curve
4. *Target properties*, which modify the curve at the small crater range
5. *Mapping and counting* (average and distortion), when geologic boundaries are ignored

The implications will be discussed in further detail at the end of this chapter.

The statistics of cratering on planetary surfaces are commonly described by the shape of the SFD (e.g., **Figure 6**). The theoretical concept and mathematical background for dating techniques based on crater counts were developed in the 1960s and 1970s, as summarized by the *Crater Analysis Techniques Working Group* (Arvidson et al., 1979). Histogram graphs, used to display crater statistics, plot *cumulative* crater frequencies (number of craters greater than or equal to a given size per square kilometer, N_{cum}) against the crater diameter D on log–log diagrams. Distribution characteristics are defined by polynomial functions or multiple-segment power laws, where the cumulative frequency N_{cum} is proportional to D^{-b} and b varies between 4 and 1.5. There are other representations such as *incremental*, *differential*, or *relative* (R)-plots discussed in more detail in the succeeding text.

The main observation is that small craters are significantly more numerous than large craters, reflecting the proportion of the fewer large projectiles compared with the number of small projectiles in the solar system (e.g., Baldwin, 1964), and that

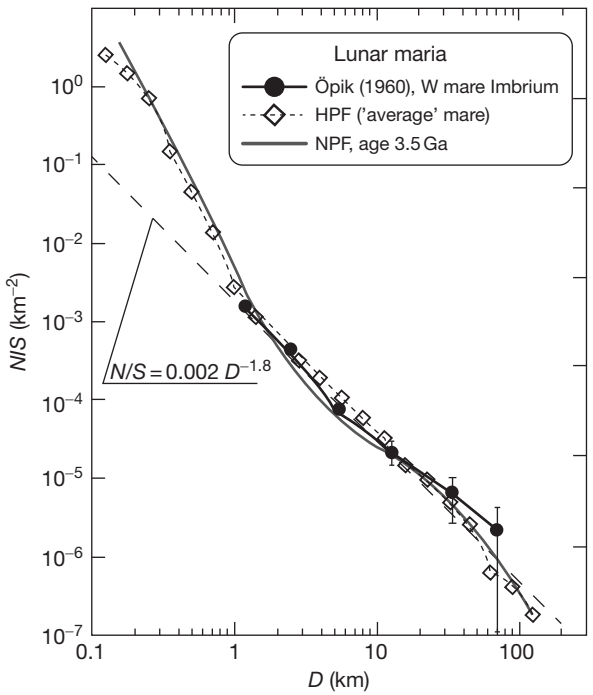

Figure 6 The early cumulative crater count (Öpik, 1960) on the lunar nearside in comparison with more extensive data published later.

has been recognized well before active Moon space-based exploration. Figure 6 illustrates the early crater counts on lunar maria using telescopic images of the lunar nearside (Öpik, 1960). Öpik's early data set shows that the cumulative number of craters in the diameter range from 1 to 100 km is close to a $D^{-1.8}$-dependence.

The SFD of craters or projectiles is the relation between the object size (e.g., diameter) and the number of such objects of the population investigated. There are three main styles of the SFD presentation (reviewed by the Crater Analysis Techniques Working Group (Arvidson et al., 1979):

1. *Cumulative* form of the SFD plot represent the number of craters larger than or equal to a given diameter, $N(\geq D)$.
2. *Differential* forms of the SFD plot represent the incremental number of craters in a given diameter bin (from the *left* bin-limiting diameter to the *right* bin-limiting diameter), $D_L \leq D < D_R$, as $\Delta N/(D_R - D_L)$.
3. *Logarithmic* forms of the differential SFD plot represent the incremental number of craters in a given logarithmic D-bin, where $D_R/D_L =$ constant and typically is $\sqrt{2}$. The slope (in near-linear segments) equals that of the cumulative SFD.
4. *Relative* form of the SFD plot represent the differential form, multiplied by D^3:

$$R = D_{av}^3(\Delta N/S)(D_R - D_L) \quad [19]$$

where the geometric mean interval diameter is defined as $D_{av} = (D_R \cdot D_L)^{0.5}$. The incremental number of craters is divided by the size of the counting area so that the R-value becomes nondimensional. However, for statistics of other object types, such as asteroids, the R-value can be a dimensional one. The graphic representation of the $R(D_{av})$ relations is known as the *R-plot*.

The different types of plots have different advantages and disadvantages and can be used complementarily: For example, cumulative SFD forms tend to smooth irregularities, such as deficiencies of craters in certain D-bins, and therefore, it is more difficult to detect crater obliteration processes. Because of the cumulative number, the statistical errors may become very small. Differential forms, essentially incremental histograms, have the advantage of showing the actual $N(D)$ behavior for each D-bin, including turndowns caused by crater obliteration. Conclusions derived from these plots, though, could be statistically less significant due to small-number statistics and large variance. The log differential forms have the advantage of mimicking the cumulative $N(D)$ slope, so that slopes of the distributions can easily be compared.

The ideal case to study the crater SFD is on a planetary surface that instantaneously begins to accumulate new craters and never gets modified. The observed crater SFD reflects the production SFD or *the standard distribution* of the projectiles. In natural cases, crater degradation and other obliteration processes change the population of these craters. To derive a production function from natural examples of crater SFD measurements, many authors have tabulated and generalized lunar crater counts. Early results are presented, for example, by Hartmann (1969), Hartmann (1970a), Neukum et al. (1975a,b), and Neukum (1983) and summarized in an early review paper by Hartmann et al. (1981), which developed into the two most commonly used varieties of the crater-based age-determination method. Therefore, we concentrate in this chapter on these two lunar *production* crater SFDs as they were proposed by Hartmann and Neukum (see details in Neukum et al. (2001a)) and then updated by Hartmann (2005). They are well described and easy to implement. The term *production function* of a specific age, or the *isochron*, has been defined as the SFD of craters forming on planetary surfaces for the period the planetary surface was exposed, which defines the age of the surface (e.g., Neukum and Ivanov, 1994; Strom et al., 1992).

10.10.5.2 Hartmann Production Function

In his work on crater SFDs, Hartmann focused on the Moon and Mars. He describes the observed crater distributions in a log-incremental representation with a standard $\sqrt{2}$-diameter bin size. The number of craters per square kilometers, here, is calculated for craters in the diameter bin $D_l \leq D < D_R$, where D_L and D_R are the left and right bin boundary and the standard bin width is $D_R/D_L = 2^{1/2}$. For the Moon, Hartmann defined power-law descriptions for three diameter intervals (Hartmann, 1999):

$$\log N_H = -2.198 - 2.20 \log D_L \quad \text{for } D_L > 64\,\text{km} \quad [20a]$$

$$\log N_H = -2.920 - 1.80 \log D_L \quad \text{for } 1.41\,\text{km} < D_L < 64\,\text{km} \quad [20b]$$

$$\log N_H = -2.616 - 3.82 \log D_L \quad \text{for } 0.3\,\text{km} < D_L < 1.41\,\text{km} \quad [20c]$$

Hartmann used for the larger craters ($D > 4$ km) an exhaustive catalog of individual crater-by-crater diameters, measured by Arthur et al. (1963, 1965a,b, 1966), documented in Figure 4 of Hartmann (2005), to determine an average mare production distribution. The condition to have a uniformly fresh surface is nearly satisfied by the fact that most lunar mare basalt samples have a narrow range of ages (i.e., 3.2–3.6 Ga; Hiesinger et al., 2003; Stöffler and Ryder, 2001), although the flux of crater-forming projectiles during that period dropped by a factor of 2–3. The observed crater distribution of the mare units reaches a saturation equilibrium areal density above crater diameters of $D \sim 300$ m (Hartmann, 1984). The assigned age for the average mare distribution was in later publications modified from 3.4 to 3.5 Ga (Hartmann, 2005; Hartmann and Neukum, 2001).

Deriving Mars isochrons, Hartmann refined his approach over some years by a set of iterations (1999, 2002, and 2004) (Hartmann, 2005; Hartmann and Neukum, 2001). He started by extrapolating the lunar slope for the diameter range of craters smaller than 300 m according to eqn [20c] (iteration 1999) and subsequently by adopting a continuation of the curve by grafting on the shape at the small-diameter end of the crater-production function as described with the polynomial expression by Neukum (e.g., Neukum and Ivanov, 1994). The slope representing the polynomial expression in that diameter range is the −2.9 cumulative slope (Shoemaker et al., 1970):

$$\log N_H = -2.0 - 2.90 \log D_L \quad \text{for } 0.01\,\text{km} < D_L < 0.125\,\text{km} \quad [20d]$$

Subsequently, Hartmann (2005) adjusted the iteration 2002 shape by the effects of atmospheric shielding for small Martian impact craters as it is calculated by Popova et al.

(2003). We call this result the *Hartmann production function*. The calibration of the absolute ages, and the calculation of the isochrons as examples are given in **Figure 7**, will be discussed in the succeeding text.

10.10.5.3 Neukum Production Function

A number of studies of the lunar crater SFD revealed that there is no unique power law to present the crater SFD in the whole range of crater diameters (Chapman and Haefner, 1967). Instead of using power-law segments such as Hartmann, Neukum et al. (1975a) proposed an analytic function to describe the cumulative number of lunar craters, N, per square kilometer with diameters larger than a given value D. They computed a polynomial of 7th degree by a least-square fit for a crater diameter range between 300 m and 20 km. In a series of publications – (see summary by Neukum and Ivanov, 1994) – this polynomial was extended to the 11th degree and for a diameter range between 10 m and 300 km. They proposed this polynomial to be applicable, considering crater scaling, on all terrestrial planets, asteroids, and some moons, and it is expressed by

$$\log_{10}(N) = a_0 + \sum_{n=1}^{11} a_n \log_{10}(\mathrm{D}^n) \qquad [21]$$

with $0.1\ \mathrm{km} < D < 300\ \mathrm{km}$ validity range for the Moon, where D is in kilometers, N is the number of craters with diameters $\geq D$ per square kilometers per billion of years, and the coefficients a_n are given in **Table 1** for the Moon. Recently, the coefficients were slightly reworked for the largest crater range by careful re-measuring in the size range (Neukum et al., 2001a). We call this result the *Neukum production function*. The time dependence of the a_0 coefficient is discussed in the following subsection.

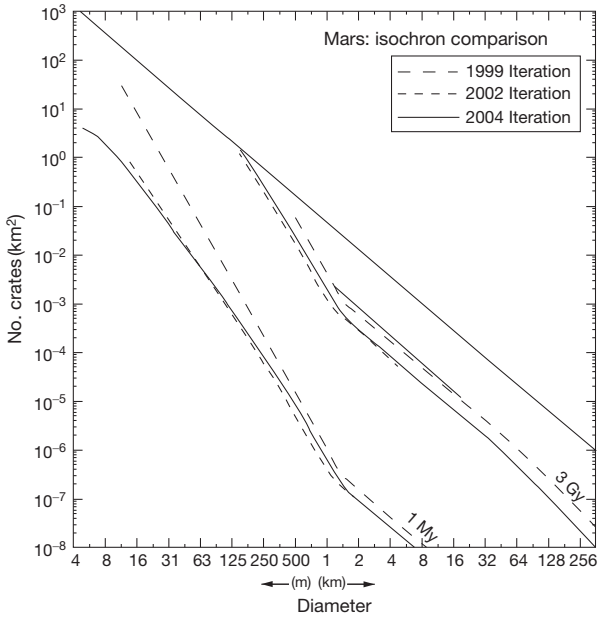

Figure 7 Iteratively evolved isochrons for 1 Ma and 3 Ga of the Hartmann scheme in comparison. Source: http://www.psi.edu/epo/isochrons/chron04b.html.

Although the shapes of both types of crater-production functions differ for crater diameters larger than 1 km and vary significantly for crater diameters between 2 and 25 km (e.g., Ivanov, 2001; Werner and Tanaka, 2011), they show a rather similar overall behavior (**Figure 6**). Despite the individual approach of these models, both assume that the general shape of the crater-production function for objects striking the Moon stayed the same for at least the past 4 Gy. This point of view has been challenged over the years, mostly by Strom (Strom and Neukum, 1988; Strom et al., 1992, 2005), who suggests that the modern (post-mare formation) production function is different from that produced during the epoch of the LHB (before about 3.9 Ga ago). Similarly, modern numerical models for the dynamical evolution of small bodies in the solar system support the possibility that the velocity and SFD of the projectiles may vary throughout the first billion years of solar system evolution (e.g., Bottke et al., 2012; Morbidelli et al., 2012b).

Several issues can occur in case of long-term exposure to cratering of a planetary surface. From the very beginning of the impact crater population studies, it was recognized that ongoing bombardment of a given surface with low little endogenic activity (like on the Moon) impact craters would cover the entire surface, so that any new crater formed would destroy older craters. Hence, the areal crater density (number of craters of a given size per unit area) stops to grow, reaching some maximum value defining the state of the so-called saturation equilibrium (various authors use this term or prefer to say briefly 'saturation state' or 'equilibrium state'). After the pioneering physical modeling by Gault (1970), many publications have clarified this problem, and are reviewed in the introductory part of the paper by Richardson (2009). Briefly, the study revealed two main mechanisms that limit the number of craters to be counted at or near the saturation limit. If the production function is *steep* ($N \sim D^{-n}$, $n > 2$), small craters tend to erase larger craters ('sandblast regime'). The steep production function is typical for lunar craters smaller than ~1.5 km. The sandblast regime results in the limiting slope of the crater SFD of $N \sim D^{-2}$ for all slope indices $n > 2$.

Table 1 Coefficients for eqn [21] for the lunar case

a_n	N_{cum} (D) (Neukum, 1983)	N_{cum} (D) (Neukum et al., 2001a)	Sensitivity (%)[a]
a_0	−3.0768	−3.0876	
a_1	−3.6269	−3.557528	±3.8
a_2	+0.4366	+0.781027	±3.9
a_3	+0.7935	+1.021521	±1.6
a_4	+0.0865	−0.156012	±1.6
a_5	−0.2649	−0.444058	±0.88
a_6	−0.0664	+0.019977	±1.3
a_7	+0.0379	−0.086850	±0.78
a_8	+0.0106	−0.005874	±1.8
a_9	−0.0022	−0.006809	±1.8
a_{10}	-5.18×10^{-4}	$+8.25 \times 10^{-4}$	±5.6
a_{11}	$+3.97 \times 10^{-5}$	$+5.54 \times 10^{-5}$	±24.1

[a]Sensitivity is the coefficient variation, which changes the N_{cum} (D) value a factor of 2 up and down.

For *shallow* production functions ($N \sim D^{-n}$, $n \leq 2$), the main mechanism is the episodic renovation of the area by the largest crater (the so-called cookie-cutting regime). After a regionally critical impact event, the adjacent area is renovated by the ejecta blanket and the fresh surface starts to accumulate craters again. The SFD of craters near equilibrium in the cookie-cutting regime reproduces the primary production function shape (Chapman and McKinnon, 1986; Woronow, 1978). This situation is observed in heavily cratered lunar highlands. The modern modeling e.g., Richardson, 2009 included more sophisticated models of crater evolution (like downslope motion from the crater wall) confirms that the shallow part of the primary production function should be still visible at heavily cratered terrains. However, these modern models do not include a possible change in the target properties as the upper layers are progressively affected by multiple impacts. More refined models should be constructed to take into account higher target temperature of the Moon during the earliest bombardment period (this may affect the largest craters; e.g., Ivanov et al., 2010b) and the subsequent decay of the bombardment rate (e.g., no basins younger ~3.7 Ga).

One of the important features of impact craters in saturation is their less-random distribution at the surface (Squyres et al., 1997). Primary impacts usually occur in random spots at the surface. The statistics of center-to-center distances may be mathematically simulated with by a random process. Craters in saturation (meaning: recognizable craters) reveal center-to-center distance statistics shifted to a more regular spatial distribution. Such features are not studied in the modeling approaches mentioned in the preceding text. Only few papers take this statistics into account (e.g., Michael et al., 2012).

A rule of thumb was proposed by Hartmann (1984) to draw a single power-law SFD for craters in the saturation/equilibrium with a relation of $N \sim D^{-1.83}$, which can be used for a primary visual inspection of the closeness to the equilibrium. In the notation explained in **Section 10.10.5.2**, Hartmann's empirical saturation line is expressed as $\log N_H = -1.83 \log D\,(\mathrm{km}) - 1.33$.

10.10.6 Impact Rate Estimates

Impact rate estimates for the earliest evolution of solar system planetary bodies can be obtained only from models, and thus, they depend on the theoretical concept of solar system evolution, assuming that the bombardment history of the Moon is closely related to our understanding of planetary formation and evolution of the solar system. For the period about 4.1 Ga and younger, rates can be determined by correlating crater frequencies measured near Apollo and Luna sampling sites and absolute apparent ages for the returned samples. Among others (Baldwin, 1971; Bloch et al., 1971; Hartmann, 1970a; Neukum et al., 1972; Soderblom and Boyce, 1972), both Hartmann (1970a) and Neukum et al. (1975a) had shown that crater densities at lunar landing sites of different ages require that the cratering rate decreased by a factor of 100 between 3.9 and 3.3 Ga ago, implying a cratering-rate half-life of the order of 10^8 years. This permitted dating of surface features so that the planetary evolution could be studied through geologic time.

Modern impact rates on planets, considered for the period from about 3 Ga ago to today, are assumed to be a result of a quasi steady-state regime. Rates are defined by orbital evolution of small bodies under weak gravitational forces including resonant perturbations of the large planets acting dominantly on asteroids in the MAB and close encounters on planets in the inner solar system, such as the near-Earth asteroids. Additionally, nongravitational (nonconservative) forces act on smaller asteroids (diameter <20 km). Such are the effects of solar radiation, which produces a radial migration if the asteroid rotates. However, collisions between asteroids, or small bodies in general, have been earlier evoked as a process that not only shaped the current and past asteroid SFD down to particles of dust size (which can be removed from the solar system by radiation pressure of the sunlight) but also could be a mechanism to change orbital parameters of fragments to replenish the *Kirkwood gaps* in the MAB orbital parameter space so that a fraction of fragments reach planet-crossing orbits, producing small meteoroids, which could be found on Earth as meteorites and crater-forming projectiles. (Kirkwood gaps are zones in the orbital parameter space, which are not populated, because objects with such a parameter range are perturbed mostly by gravitational modification due to orbital resonances with not only Jupiter but also Saturn; for more details, see **Section 10.10.5.1**.)

Collisions affect the physical state of asteroids, orbital parameters, and intrinsic angular momentum, forcing fragments into orbits that are easily affected by resonant perturbations, so that the fragments end up in planet-crossing orbits. The extreme case is a catastrophic collision, resulting in the asteroid disruption. The largest fragment is produced with a mass of one-half of the initial asteroid mass (Greenberg and Hartmann, 1977; Greenberg et al., 1978). For small asteroids (with diameters smaller than about 1 km), the resulting fragment-sized distribution is controlled mostly by the strength of the asteroid material. The effective strength is usually expressed in units of the specific energy of the impactor per unit mass of the target body. For laboratory-scale rocky model bodies, the catastrophic specific energy is in the range of 300–2000 J kg^{-1} (O'Brien and Greenberg, 2005, see summary in their Figure 4a). With increasing asteroid size, the strength of an asteroid declines slowly, because larger bodies in nature commonly contain more intrinsic defects (fractures, pores, and inhomogeneities), and thus, the resistance to deformations and fragmentation is decreased (Love and Ahrens, 1996; Ryan and Melosh, 1998). For large asteroids (with diameters of 1 km and larger), self-gravitation becomes important, keeping fragments of an impact event together, and the dispersal of fragments is inhibited. Such an accumulation of fragments, kept together due to gravity, is nicknamed rubble pile, and they are asteroids, repeatedly shattered but not dispersed. The asteroids in the size range of 200–800 m have the smallest strength against disruption (O'Brien and Greenberg, 2005, see summary in their Figure 4b).

The frequency of giant impacts in the MAB constrains the number of large crater-forming projectiles. The rarity of impacts that produce fragments larger than 1 km and divert them toward planets, as correctly pointed by Shoemaker, resulted in an early assumption that most of impact craters with diameters larger than ~30 km on terrestrial planets are

formed by comets (Shoemaker and Wolfe, 1982; Shoemaker et al., 1990). The recognition of a prevailing role of gravitational forces (resonances) in the repopulation of planet-crossing orbits from the MAB (Farinella et al., 1994) has destroyed Shoemaker's main argument for comet dominance. Modern estimate of the comet fraction in the impact cratering is about $10 \pm 5\%$ (Bottke et al., 2002, 2005; Weissman et al., 2002). Delivering frequencies derived with the Nice concept of planetary system evolution, comets play a negligible role (Bottke et al., 2012).

The lifetime of bodies at planet-crossing orbits was assumed to be controlled by close encounters with planets (Arnold, 1965; Wetherill, 1967). From the modern point of view, this model gives too high estimates of the lifetime of objects on planet-crossing orbits (Dones et al., 1999). Gravitational resonances are now seen to be a major factor in producing objects with planet-crossing orbits.

10.10.6.1 Gravitational Mechanisms

One critical mechanism in changing small-body orbits into planet-crossing orbits is the resonant perturbation of giant planets. There are two broad kinds of resonances (Morbidelli, 2002): (1) *mean motion resonances* (the periods of rotation around the Sun of two bodies give the ratio of integer numbers) and (2) *secular resonances* (the precession frequency of the asteroid's longitude of perihelion is equal to the integer number of a secular frequency of the planetary system). Especially, resonances with Jupiter create gaps, *Kirkwood gaps*, in the MAB orbit distribution as a function of semimajor axis a. The most prominent mean motion resonances with Jupiter form gaps at mean orbital ratio of 3:1 ($a = 2.5$ AU), 5:2 ($a = 2.82$ AU), and 2:1 ($a = 3.27$ AU) between the asteroid and Jupiter. For the deflection of main belt asteroids (MBA) into planet-crossing orbits, two resonances are found to be the most important, the 3:1 mean motion resonance with Jupiter and the secular ν_6 resonance with Saturn. (Michel et al., 2005). Many other resonances influence asteroid orbit evolution (Milani and Farinella, 1995; Morbidelli and Gladman, 1998).The action of resonances results in a quick increase or chaotic change of an asteroid's eccentricity, making it a planetary orbit crosser. While most of the resonant perturbations destabilize asteroid orbits, the *Kozai resonance* (which occurs when the precession of the asteroid's longitude of perihelion equals the precession of its node and keeps the quantity $a(1-e^2)^{0.5} \cos i$ constant during a planetary encounter) provides a sort of protection from close encounters. Bodies with low inclination and a semimajor axis close to that of Earth or Venus may enter the Kozai resonance, which causes the perihelion to librate around 0° or 180°. Moreover, the semimajor axis remains almost constant, which protects the body from a collision with the planet (Gladman et al., 1995; Michel and Thomas, 1996; Michel et al., 1996; Milani et al., 1989), at least temporarily.

10.10.6.2 Nongravitational Mechanisms

The orbits (1) and the rotation rates and obliquity (2) of the small bodies in the solar system may be modified by the thermal effects and the radiation forces. Both parameters are influenced by solar heat, accumulated by the day side of an asteroid and reradiated from the surface when a given area rotates to the night side (Bottke et al., 2006; Morbidelli and Vokrouhlicky, 2003; Rubincam, 1998). The effect depends on thermophysics of the thin surface layer, distance from the Sun, and obliquity of the asteroid. The modification of the orbit of a small body is called *Yarkovsky effect* (1) and acts as not only a function of size and heliocentric distance but also material properties. For a typical 1 km body, the Yarkovsky effect results in the orbital semimajor axis drift of the order of 10^{-4} AU per 10^6 years. The comparison of modeled Yarkovsky effect with astronomical observation is still limited to a few asteroid observations (Chesley et al., 2003) and statistical investigations of asteroid family evolution (Vokrouhlicky et al., 2006a,b). The Yarkovsky effect operates slowly, but it is important for the MBA evolution and delivery of small bodies to resonant orbits.

The solar-induced thermal torque may also change the rotation rate and spin axis orientation of the small body. The related *Yarkovsky–O'Keefe–Radzievskii–Paddack* (YORP) *effect* (2) explains how the solar irradiation may change the spin state (spin up or spin down) of a small body by the reflection and reradiation of absorbed sunlight (Capek and Vokrouhlicky, 2004; Rubincam, 2000). The strength of the effect depends on the size of the object and its obliquity; however, the full implications of this effect require further studies.

Both effects require too long timescales, to be considered as important delivery mechanism outside the asteroid belt. Once an object becomes a planet-crosser, the main disturbing events are encounters with terrestrial planets, and the Yarkovsky effect has no time to build up the necessary input for the orbit evolution (Michel and Yoshikawa, 2005).

While modeling the dynamical evolution from the MBA to NEO, nongravitational effects predict a steepening of NEO SFD versus the MBA SFD due to increased small asteroid *mobility* in the phase space, resulting from the Yarkovsky and YORP effects (Morbidelli and Vokrouhlicky, 2003). These effects are believed to dominate in decameter-sized range (e.g., Jedicke et al., 2002, their Figure 7) but affect different taxonomic types differently (Hartmann et al., 1999). Nongravitational effects on NEO SFDs are yet visible only as a tendency for absolute magnitudes $H < 18$. However, radiation-driven models offer progress in the understanding of asteroid family evolution (Bottke et al., 2006; Vokrouhlicky et al., 2006a,b). Being one of the fundamental causes for asteroid orbital evolution, which, thus, are important for the impact-rate discussion, the Yarkovsky and YORP effects still estimate the absolute rate of evolution with only limited accuracy, because the thermophysical properties of asteroids are poorly known. For example, the age of the Baptistina family was originally estimated in the range of 140–190 My (Bottke et al., 2007) but was later adjusted to the 140–320 My range, due to possible density ($\pm 30\%$) and thermal conductivity (factor of 3 up and down) variations (Masiero et al., 2012).

10.10.6.3 Impact Probability

The impact probability of NEOs is a parameter that connects the observed NEO population and the number of actual impact events on the target planet, measured as the recent cratering rate (e.g., Oberst et al., 2012) or as the rate of bolides recorded as light flashes (meteors or bolides or fireballs) in the

terrestrial atmosphere (e.g., Ivanov, 2006). Key assumption here is that the population of NEOs, N_{NEO}, is in a steady state. The average (for the whole NEO population) probability of collision with the target planet is P_{col} (measured in year^{-1} per one object); the impact rate, R_{col}, defined as number of impacts (collisions) in the specific time period (e.g., per year) is

$$R_{col}(\text{year}^{-1}) = N_{NEO} \cdot P_{col} \quad [22]$$

Standard approaches estimate encounter probabilities, P_{col}, according to Öpik's formulas (Bottke and Greenberg, 1993; Öpik, 1951, 1976; Wetherill, 1967) provided that the main orbital parameters for NEOs and the target planet, a, e, i, are constant in time and all angles defining mutual position of orbital planes are equally probable. Typical encounter probabilities, P_{col}, are in the range of 10^{-11}–10^{-8} year^{-1}, and during a typical lifetime of the individual NEO of 10^7 year^{-1}, the probability of impact is very low. In reality, individual objects change their orbital parameters across a wide range of the phase space during their lifetime. Hence, eqn [22] should be treated as an estimate for only a specifically populated orbit set that requires the population to be in a steady state. This state is reached if, for example, (1) an Apollo object changes its orbit to the Amor-type orbit and another NEO changes its orbit from the Amor-type to Apollo-type orbit (see Milani et al., 1989) and (2) the number of objects leaving the NEO family, for example, striking the Sun and planets or being ejected out of the inner solar system, is replenished with new NEOs arriving from the MAB orbits.

Estimates using forward integration of known objects considering perturbations as discussed in **Sections 10.10.5.1** and **10.10.5.2** also yield impact probabilities. The forward integration of Earth-orbit-crossing asteroids with $H < 18$ produces statistics of close approaches (distance < 0.1 AU) with average impact probability of all NEOs (bodies with $q < 1.3$ AU) as low as 1.7×10^{-9} year^{-1} per one NEO, which is equivalent approximately to 3.4×10^{-9} year^{-1} per individual Earth-orbit-crosser (Harris, 2003; Morrison et al., 2002; Stuart and Binzel, 2004). Most of the astronomically observed NEOs are tested by numerical orbit integration to be estimated as a potentially hazardous object (PHO). The list of PHO close encounters with Earth is published by several groups. None of the tested NEOs, according to the numerical orbital motion integration, show a chance of striking the Earth or Moon in the historically short time, with the exception of 99942 Apophis. However, highly accurate impact probability estimates require good knowledge of orbital parameter and physical properties to calculate all perturbation effects correctly. Currently, an impact probability greater than 10^{-6} is found for an impact in the year 2068 (Farnocchia et al., submitted for publication).

Parallel estimates by numerical simulations and by Öpik-type estimates for a large population of asteroids based on cratering-rate derivations may be treated as the average probability of steadily populated planet-crossing orbits. One challenge of estimating the impact probability is that the subset of orbits having the largest collision probability simultaneously are orbits with the shortest lifetime. Therefore, the high probability of a close encounter can result in either collisions or an abrupt orbit change during the close encounter. Hence, there is only a small chance to observe NEOs in these orbits. By analyzing real collisions of small and hence frequent enough bodies colliding with the Earth atmosphere and observed as bolides (Morbidelli and Gladman, 1998), the statistical investigation of impact probability for small NEOs can be extended. Systematic photographic surveys of bolides have been made in different countries in different periods of time (Borovicka et al., 2005; Ceplecha, 1987; Halliday et al., 1996; McCrosky et al., 1978; Oberst et al., 1998). Registration of each event from several observational points allows researchers to estimate orbital parameters just before the atmospheric entry. Using these orbital parameters, one can make a formal calculation of the Öpik-type collision probabilities and compare these estimates with similar values for astronomically observed NEOs, by assuming an appropriate NEO SFD. The latter is one of the crucial reasons why these bolide impact probability data may be diverting from large astronomically observed objects. Only NEOs with diameter of ~1 km and larger have close to complete statistics, but the statistics of bolides for small bodies with the effective diameter of a few meters and smaller are nearly undetermined (see discussion by Morrison et al., 2002). The Chelyabinsk meteor (15 February 2013) unexpectedly entered the atmosphere and exploded, making it the most recent and prominent example of undiscovered small projectiles. In addition, there are many inherent observational biases for bolide observations as a statistical database (Halliday et al., 1996). To reduce the severity of possible biases, estimates for bolides with various minimum photometric mass (0.1, 1.0, and 10 kg) from the database for bolides from many surveys need to be considered (Lindblad et al., 2003). Recent long-term and high-resolution space-based image coverage of the Moon and Mars allows discovering newly formed impact sites, which allow adding more numbers to the impact probability at the small-sized range of planet-crossing objects (Daubar et al., 2013; Oberst et al., 2012). As for all these estimates, uncertainties determining the projectile size are given, due to atmospheric breakup, crater scaling laws, and general unknown observational bias, as well as the challenge to link the SFD of these meter- or less-sized objects and the astronomically observed kilometer-sized NEO population (e.g., Morrison et al., 2002).

To check the idea that the small number of meteoroid collision with Earth occurs from a small number of orbits with high impact probability, data for NEOs and bolides are sorted in the order of increasing P_{col} with calculation of the accumulated average $<P_{col}>$ for the meteoroid ensemble:

$$<P_{col}(n)> = \frac{\sum_{i=1}^{n} P_{col,i}}{n} \quad [23]$$

where i is the number of the orbit ($i = 1, N$) and $P_{col,i}$ and $<P_{col,i+1}$. In this construction, first, the lowest-probability orbits are summed and the average value grows as $P_{col,i}$ monotonically increases with the number i in this sorted list. If a low number of orbits with higher collision probability give disproportional large input, the function $<P_{col}(n)>$ would rise when n approaches the total number of recorded events, N. **Figure 8** presents the relation between $<P_{col}(n)>$ and $P_{col,n}$, the largest probability in the partial sum in eqn [23] for Earth-crosser objects in asteroid-like orbits ($T_J > 3$, calculated according

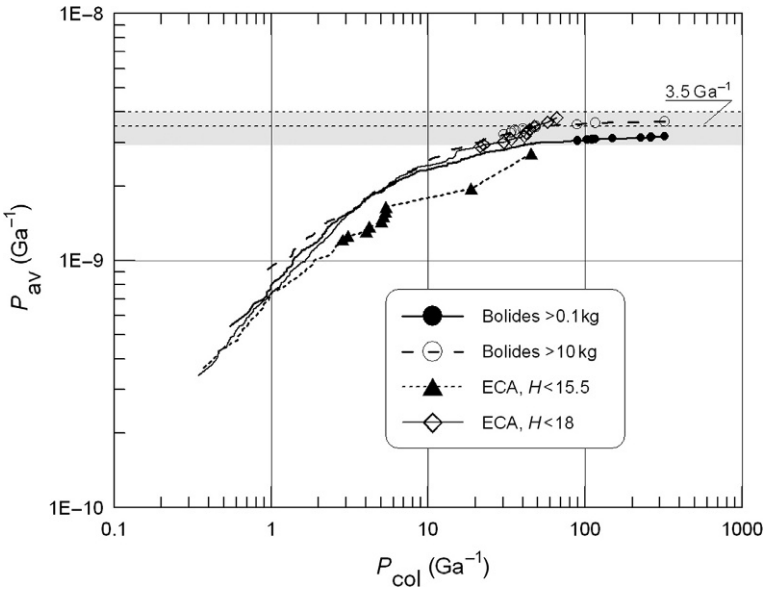

Figure 8 The accumulated sliding average for Earth-crossing asteroids (ECAs) and bolides, constructed by sorting the orbits according to their ascending collision probability (eqn [23]). All curves flatten for sparsely populated orbits with large collision probabilities. The average probability for the whole observed population is about 3.5 ± 0.5 Ga^{-1} per one Earth-crosser. For each data set, ten events with the largest collision probability are marked, to illustrate their importance.

Table 2 Estimates of collision probability and average impact (preatmospheric) velocity of bolides from meteor ground surveys

	Known Earth-crossers		*Observed bolides*		
	H < *18*[a]	H < *18*[b]	m_{ph} > *10 kg*[c]	m_{ph} > *1 kg*[c]	m_{ph} > *0.1 kg*[c]
$T_J > 3$					
N	401	461	74	152	227
P_{col}, year^{-1}	3.8×10^{-9}	3.52×10^{-9}	3.7×10^{-9}	3.2×10^{-9}	3.2×10^{-9}
$<U>$	19.0	19.0	19.0	19.8	20.3
$2 < T_J < 3$					
N (% of total)	54 (12%)	94 (17%)	18 (20%)	48 (24%)	106 (32%)
P_{col}, year^{-1}	0.80×10^{-9}	0.94×10^{-9}	0.88×10^{-9}	0.90×10^{-9}	0.93×10^{-9}
$<U>$	26.4	24.6	27.5	25.2	25.5
All objects with $T_J > 2$

[b]Column as the MPC catalog (file 'astorb.dat') in February 2013.
[c]IAU MDC Photographic Database, Version 2003, (Lindblad et al., 2003).

eqn [24] in the succeeding text) with *absolute magnitudes* (the absolute magnitude of asteroids, H, is defined as the apparent magnitude that the object would have if it was one astronomical unit (AU) apart from both the Sun and the Earth and at a phase angle of zero degrees) $H < 15.5$, for which completeness is assumed, and $H < 18$ (roughly >1 km in diameter, as of February 2013) objects and for fireballs with photometric masses more than 0.1 and 10 kg (as of 2003; Lindblad et al., 2003). One can see that the function $<P_{col}(n)>$ for $H < 15.5$ bodies and fireball meteoroids grows smoothly to the average collision probability per object of 3.5 ± 0.5 Ga^{-1}. These curves flatten for the largest probabilities, converging to the limiting average probability. Data for $H < 18$ objects may be corrected for the incompleteness of astronomical survey for these bodies. Possible undiscovered bodies with $H < 18$ will have orbits with small collision probabilities (low probability of close encounters) (compare Table 2), and therefore, the average collision probability will decrease, because a larger number of bodies with assumed low collision probabilities do not essentially add to the sum of individual orbital collision probabilities.

Celestial mechanics reveals two broad classes of orbits of small bodies in the solar system depending on whether the

orbit allows close encounters with Jupiter or not. Astronomically recent close encounters are reflected by the specific value of the Tisserand parameter

$$T_J = a_J/a + 2\cos I\left[\left(1-e^2\right)\left(a/a_J\right)\right]^{1/2} \quad [24]$$

where a, e, i are, correspondingly, semimajor axis, eccentricity, and inclination of the small-body orbit and a_J is the semimajor axis of Jupiter.

Table 2 compares Öpik-type collision probability estimates for orbits of observed bolides (as of 2003) and similar estimates for large Earth-crossers with $H<18$ (as of 2005 and 2013). Estimates show that for objects (meteoroids) in asteroid-like orbits ($T_J>3$), the average collision probability and average collision velocity for meteoroids, observed bolides entering the terrestrial atmosphere, are close to values for known Earth-crossers, with $P_{col}\sim(3\text{–}4)\times10^{-9}$ year^{-1} per body and $<U>\sim$19–20 km s^{-1}. This corresponds well with the results of orbital integrations and bias-corrected estimates (Morrison et al., 2002; Stuart and Binzel, 2004). Objects on comet-like orbits ($2<T_J<3$) appear to grow in proportion for smaller-sized objects, less than 20% for NEOs with $H<18$ to more than 30% for bolides with small photometric masses. An observational bias cannot be excluded and deserves still further investigation. The average collision probability, P_{col}, is significantly lower, and the average impact velocity, $<U>$, is slightly higher for objects on comet-like orbits, with P_{col} of about 0.9×10^{-9} year^{-1} per body, and the average velocity ranges between 25.5 and 27.5 km s^{-1}. The average values, especially for the collision probability, for all Earth-crossing asteroids and largest bolides are slightly different due to proportion of bodies striking Earth from asteroid-like and comet-like orbits (Table 2).

We can conclude that collision probability estimates based on fireball and observed asteroid databases are consistent and that observed and documented fireball data are in agreement with the celestial mechanics results. Similar estimates of collision probabilities for the other terrestrial planets are compared in Table 3. The collision probability and average impact velocity estimates are based on the known population of planetary crossers with $H<17$.

One can state that the bolide ratio within a factor of 2 is the same for Mercury, Venus, Earth, and the Moon. Mars, being close to the MAB, suffers three to four times more frequent impacts. However, the larger surface gravity and smaller average impact velocity on Mars in comparison with the Moon result in smaller crater sizes, created by projectiles of a given size. Hence, the ratio of the cratering rates and the frequency of the same crater size formation at the unit surface area on Mars and the Moon is smaller than the bolide ratio. Thus, the formation of an impact crater of a given size on Mars needs larger, consequently less numerous, projectiles than on the Moon (Ivanov, 2001).

10.10.7 Extraterrestrial Surface Dating

10.10.7.1 Principles of Surface Dating by Crater Counting

The extraterrestrial surface dating method, which is based on cratering statistics, has been developed by several groups since the early 1960s (Öpik, 1960). Dating of cratered planetary surfaces requires combining the information from geologic mapping and crater count statistics. Mapping delineates materials by geomorphic, multispectral, or reflectance features based on natural breaks in the rock sequence, while crater count statistics provide a quantitative tool for defining relative ages and absolute model ages. The theoretical concept and mathematical background for dating techniques based on crater counts were developed in the 1960s and 1970s, as summarized by the *Crater Analysis Techniques Working Group* (Arvidson et al., 1979). The determination of absolute model ages on the Moon (and other solid surface objects) is based on the application of a crater-production function (Section 10.10.4; several examples for the Moon are shown in Figure 9) and a cratering chronology model (Figure 10, for the Moon, e.g., by Stöffler and Ryder, 2001). The crater-production function describes the expected crater SFD observed on a geologic unit at a specific time and is, when scaled, similar for all planetary bodies (e.g., Hartmann, 1973, 1977; Hartmann and Neukum, 2001; Hartmann et al., 1981; Ivanov, 2001; Ivanov et al., 2001;

Table 3 Average impact probability and average impact velocity on terrestrial planets for observed planetary crossers $H<17$, listed in the MPC catalog in February 2013

Planetary body	$N_{H<17}$	*Impact rate*[a] *(averaged)* (10^{-15} *km*$^{-2}$ *year*$^{-1}$)	*Collision probability per one body (planetary crosser, averaged)* (Ga^{-1})	*Impact velocity (averaged)* (km s^{-1})	R_b[b]
Mercury	31	0.684	1.651	34.0	0.82
Venus	95	1.002	4.856	23.3	1.20
Earth	207	1.398	3.454	19.1	1.67
The Moon	207	0.835	0.153	17.2	1
Mars, $e=0.0934$ current orbit	3159	4.248	0.195	9.6	5.09[c]
Mars, $e=0.005$[d]	1684	2.717	0.234	10.2	3.25[c]
Mars, $e=0.001$	1013	2.282	0.326	10.5	2.73[c]

[a]Average impact rate is the global number of impacts per time unit, divided by the surface area of a planet.

[b]The bolide ratio is the ratio of the impact rate of projectiles of the same size per unit area to the same value for the Moon (for the Moon $R_b=1$ by definition).

[c]Not corrected for the incomplete observation of Mars-crossers (see Ivanov, 2001, for an example of the correction).

[d]This value of eccentricity is close to the average value for a time span of 10 Ma, still limited to the available Mars orbit modeling duration (Ward, 1992).

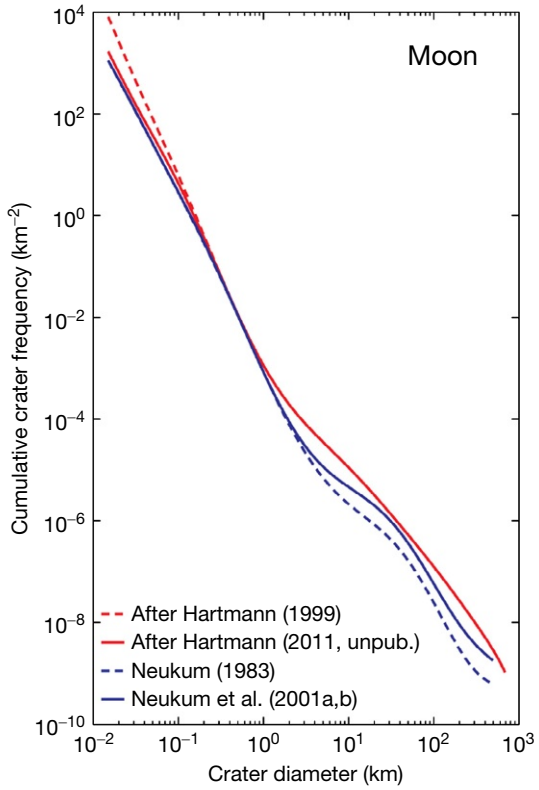

Figure 9 Four different cumulative crater size–frequency distribution (SFD) shapes in log–log scale for the Moon.

Neukum and Hiller, 1981; Neukum and Ivanov, 1994; Neukum and Wise, 1976; Soderblom et al., 1974; Strom et al., 1992).

The scaling of crater sizes between planetary bodies requires knowledge of (1) the flux ratio of impactors at different sizes considering celestial mechanical aspects (**Section 10.10.5**) and (2) how the conditions of crater formation differ from one planet to another (**Section 10.10.3**). These conditions are mainly defined by the mass of the projectiles, impact velocities, impact angles, gravity acceleration, and target properties of the impacted bodies. In the last decades, scaling laws were derived from low-velocity laboratory-scale experiments with the theoretical extrapolation to realistic impact velocities and large projectile diameters (e.g., Holsapple, 1993; Holsapple and Housen, 2007; Holsapple and Schmidt, 1987; Housen and Holsapple, 2003; Schmidt and Housen, 1987). Computing power and numerical models allowed also improving the extrapolation of experimental data to any scale of impact including the basin-forming impacts (Ivanov, 2006, 2008; Ivanov et al., 2010a,b).

Relative ages can be converted into absolute age estimates using a chronology model (exemplified in **Figure 10**), by assuming that (1) the crater-production function (the original projectile SFD) is accurately known and stable with time, (2) the flux of projectiles onto the surfaces is isotropic, and (3) target-property variations across the target body are negligible. Therefore, the crater densities measured on planetary surfaces that have been exposed for the same duration are assumed to be similar for all planetary bodies.

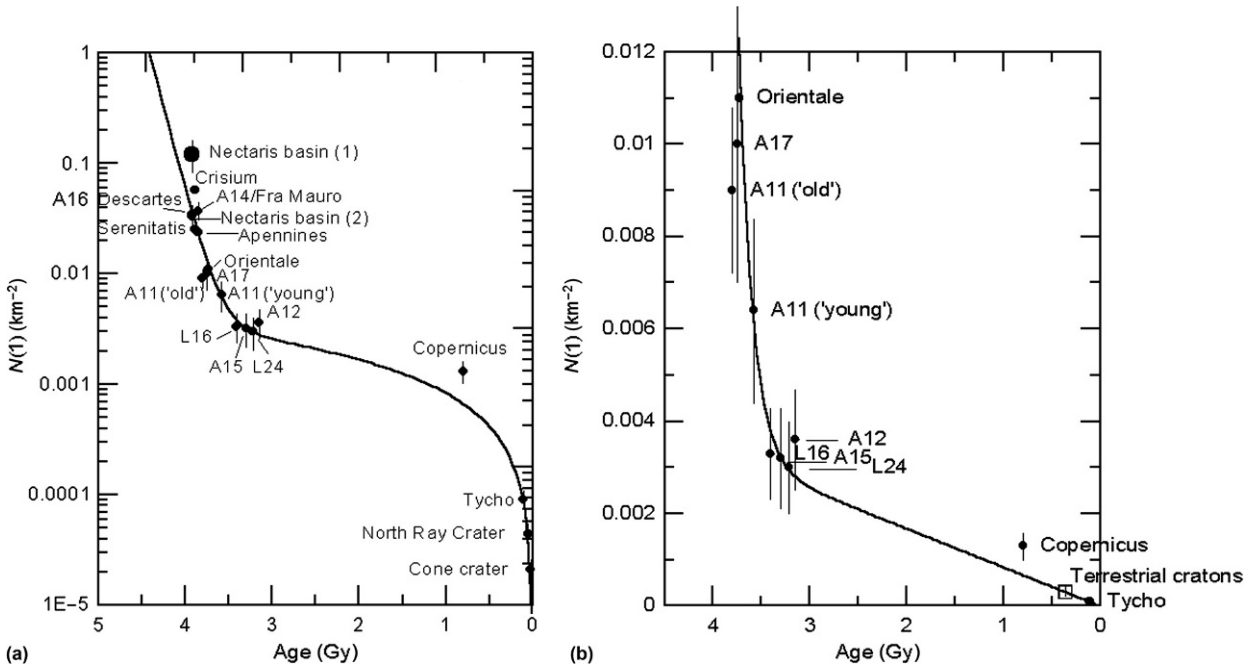

Figure 10 The accumulation rate of lunar impact craters, described as the number of craters with $D = 1$ km, $N(1)$, estimated by fitting real crater counts with a production function, (a) a semilogarithmic plot, (b) in a linear scale for younger crater population. Crater counts and sample ages are from Neukum et al. (1975b), Neukum and Ivanov (1994), Stöffler and Ryder (2001), redrafted after Neukum et al. (2001a) and Table 4 of Stöffler and Ryder (2001).

10.10.7.2 Uncertainties and Issues of the Crater-Based Surface Dating Method

As discussed in Section 10.10.4 and documented in Figures 6, 7, and 9, different authors and groups have developed SFDs for lunar and other planetary cratered surfaces. Two most commonly used varieties of the crater-based age-determination method have been derived by Neukum and Hartmann. The shapes of their crater-production functions differ for crater diameters larger than 1 km and vary significantly for crater diameters between 2 and 25 km (Figure 9; e.g., Ivanov, 2001; Werner and Tanaka, 2011). Fitting differently shaped crater-production functions to the same crater density measurements of the lunar sampling site-related geologic units results in contrasting estimates of the projectile fluxes. As an example, fitting different crater SFDs to the same original measurements of crater superposing the Apollo 16 landing site is shown in Figure 11. The Apollo 16 landing site samples are associated with the Nectaris basin, and thus, its formation age and superposed crater frequencies are considered as one of the key calibration points for the lunar evolution and the cratering chronology models.

Figure 12 shows the effect of different flux estimates at different reference diameters on the derivation of cratering chronology models, while the isotope ages are kept the same for all. The previously described example for the Nectaris basin is marked by a vertical dashed line. Application of these models leads to very diverse interpretations of the (earliest) evolutionary history of the Moon although based on exactly the same observations.

Despite the great variety of models, traditionally, in the crater-based age-determination these models share, one common feature, which is the assumption that the cratering-rate decays smoothly and monotonically. For example, no spike in cratering rate is assumed during the LHB period at about 3.9 Ga (e.g., Baldwin, 1974; Wetherill, 1975). A monotonic extrapolation for times prior about 4.1 Ga (the assumed and debated date for the Nectaris basin formation on the Moon) is used. Restricted by the maximum observed crater density (Figure 12), rarely ages earlier than ca. 4.2 billion years are found, while dated lunar samples suggest solid surface formation as old as 4.47 ± 0.07 Ga (Nyquist et al., 2010). However, also recent Nice models (e.g., Morbidelli et al., 2012b) do not provide such old ages. The shape of the curve may be distorted by considering large and small crater diameters separately, and this is reflected in the diversity of shapes of the various models. Nevertheless, this fact led to the idea that the projectile population changed over time (Fassett et al., 2012a,b; Head et al., 2010; Strom et al., 2005; Werner, 2008), which violates the traditional postulate that the source region of the projectile population, planetary orbits, and the mass distribution within the solar system have never been reconfigured over its lifetime.

Marchi et al. (2012a) argued for the significance of velocity effects for craters around 45–60 km diameter on about 4 Ga old lunar surfaces, resulting from the postulated 'Nice event' during the migration of giant planets. This migration modified the probable source regions of the impacting bodies, and thus with time, the average impact velocities were changed (Bottke et al., 2012; Morbidelli et al., 2012b). Marchi et al. (2012a) considered modern SFD of the MABs and accounted for processes that transported the asteroids from the MAB into the inner solar system. Yet this study is based on Lunar Orbiter Laser Altimeter (LOLA) topography maps, for which the craters below 60 km are not satisfactorily recognized (Figure 13).

Moreover, Marchi et al. (2012a) used the scaling law for transient crater diameters (Schmidt and Housen, 1987) $D_{tc} \sim U^{0.44}$ (eqn [10]), while for complex craters, the crater widening during the collapse stage results in a different velocity exponent $D \sim U^{0.528}$ (eqn [16]). The impact velocity difference proposed by Marchi et al. (2012a) for 'old' (pre-'Nice event')

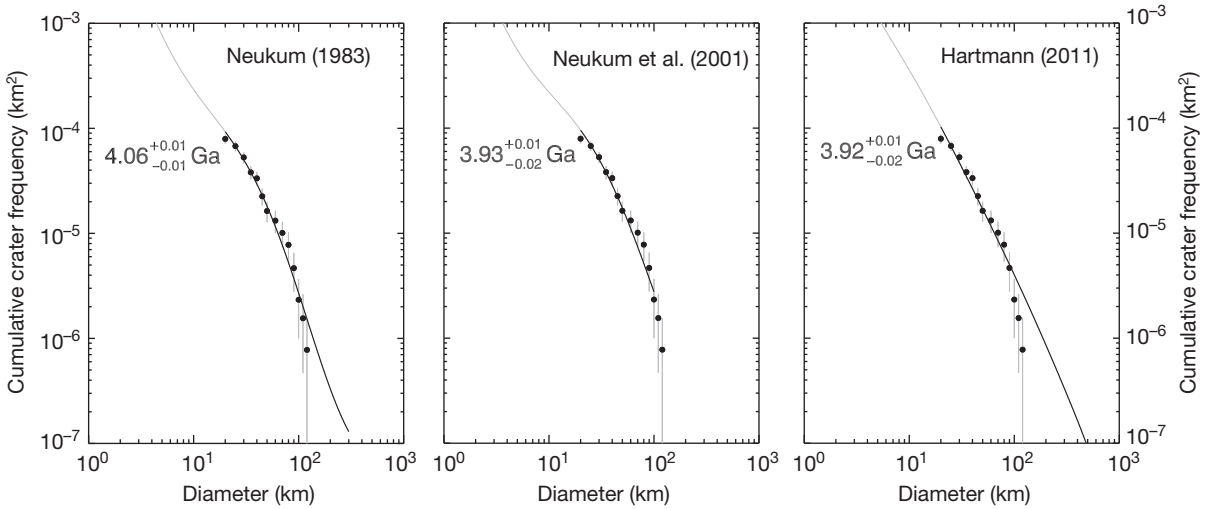

Figure 11 Fit of three different crater-production functions (**Figure 10**) by Neukum (1983), Neukum et al. (2001a,b), and Hartmann (2011, personal communication) to the same measurement of the Nectaris superposed craters (Neukum et al., 1975a,b). The measurement is used for the original calibration of the cratering chronology model by Neukum (1983). The ages (determined all with the same chronology model) reflect the variations in the extrapolated cumulative crater frequency for craters of diameters of 1 km and larger and, therefore, the need for adjusting the chronology model to reproduce the correct isotope age associated with the Nectaris basin formation age. However, additional uncertainties in the isotope age association are so far neglected.

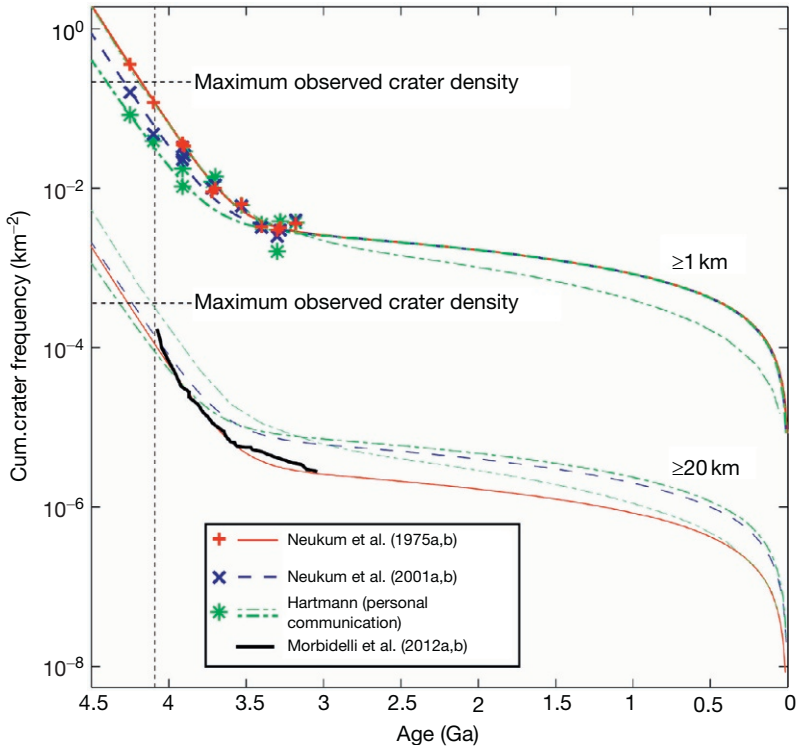

Figure 12 Cratering chronology models derived for four different lunar crater-production function curves (see **Figure 9**) shown for $D \geq 1$ km and ≥ 20 km. The Nice model (Morbidelli et al., 2012c) calibrated and therefore best-fit to the chronology model from Neukum et al. (1975a,b) is compared with the latter (Werner, unpublished). Age variations are depicted in **Figure 11**, if adjustments of the chronology models according to the specific size–frequency are ignored.

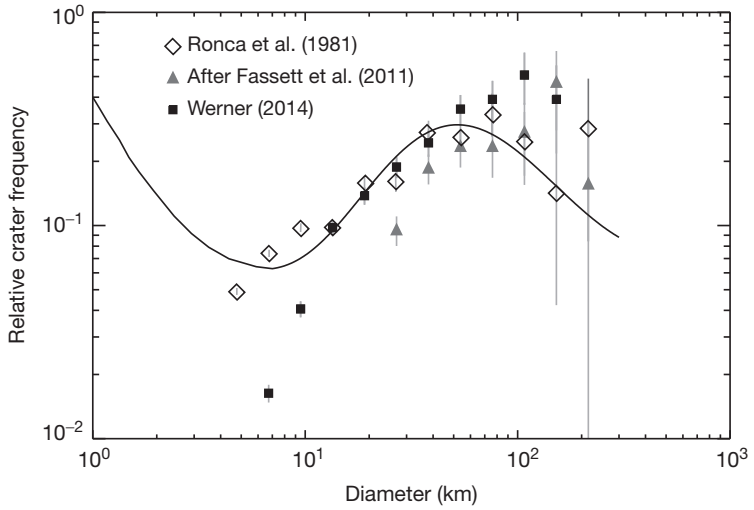

Figure 13 Example of relative (to $N_{cum} \sim D^{-3}$) crater frequencies on the Moon. Counts on LOLA topographic data (triangle) underestimate craters in the range below 60 km compared to images (diamond, square).
